We propose a language that expresses uniformly queries and updates on knowledgebases consisting of finite sets of relational structures. The language contains an operator that “inserts” arbitrary first-order sentences into a knowledgebase. The semantics of the insertion is based on the notion of *update* formalized by Katsuno and Mendelzon in the context of belief revision theory. Our language can express, among other things, hypothetical queries and queries on recursively indefinite databases. The expressive power of our language lies between existential second-order and general second-order queries. The data complexity is in general within polynomial space, although it can be lowered to co-NP and to polynomial time by restricting the form of queries and updates. © 1997 Academic Press

1. INTRODUCTION

It is a fact in database theory that as soon as the data model becomes slightly more general than a simple relational structure—for example, if one allows views in addition to stored relations—it becomes difficult to give meaning to updates [BS81, FUV83, FKUV86]. For a typical example, suppose the database is represented by the theory $\{A, B, A \wedge B \rightarrow C\}$. Let the update request be the “insertion” of the sentence $\neg C$. Then simply adding $\neg C$ to the theory results in inconsistency. Reasonable ways to incorporate the request could result in $\{A, A \wedge B \rightarrow C, \neg C\}$,

$\{B, A \wedge B \rightarrow C, \neg C\}$, $\{A, B, \neg C\}$, or the disjunction of the three.

The update problem is not unique to database theory. One also encounters it in artificial intelligence [Rei92] and in belief revision theory [Mak85, Gär88]. The common fundamental question is: What should be the result of changing a theory T with a sentence ϕ ? The departure point of belief revision theory is the *rationality postulates* proposed by Alchourrón, Gärdenfors and Makinson [AGM85], and colloquially known as the *AGM postulates*. These are principles that every adequate belief revision operator should be expected to satisfy. For example: the new fact ϕ must be a consequence of the revised theory. And: if the new fact ϕ is consistent with T , then the result should be logically equivalent to $T \cup \{\phi\}$.

However, Katsuno and Mendelzon point out in [KM91a] that all of these postulates are not universally desirable for all kinds of belief revision applications. In particular, Katsuno and Mendelzon distinguish two kinds of theory change operations, *update* and *revision*. Update consists of bringing the knowledgebase up to date when the world described by it changes. For example, most database updates are of this variety, e.g. “increase Joe’s salary by 5%.” The second type of modification, *revision*, is used when new information is obtained about a static world. We may for instance be trying to diagnose a faulty circuit and wanting to incorporate into the knowledgebase the results of successive tests, where newer results may contradict old ones. The following is an example of revision:

EXAMPLE 1.1. Suppose two robot vehicles V and W are orbiting Venus. We have received the message “I have landed,” but due to noise we could not determine whether

it came from V or W . Let v be the proposition “ V has landed” and w “ W has landed.” After receiving the message, the knowledgebase T is the theory $\{(v \wedge \neg w) \vee (\neg v \wedge w)\}$. Suppose we now send the command “Land immediately” to V , and then V replies “I have landed.” This change can be modeled by incorporating the sentence v into T . Since v is consistent with T , the *AGM* postulate cited above says the result should be equivalent $T \cup \{v\}$, which is equivalent to $\{v \wedge \neg w\}$. But upon reflection it becomes clear that this is incorrect. After V has landed, all we know is that V has landed; there is no reason to conclude that W has not. The correct answer should be $\{v\}$.

The authors of [KM91a] came to the conclusion that the *AGM* postulates describe only revision, and gave a modified set of postulates that characterize update operators (the *KM* postulates).

Suppose now we want to define a language for expressing updates to databases. It seems that in defining such a language we have first to decide whether to use update or revision, or both. But, as it turns out, Gärdenfors [Gär88] has shown that if a logic has a semantics built upon Boolean algebra, then there is no way of defining a language based on revision that does not lead to triviality. On the other hand, Grahne [Gra91] has axiomatized a nontrivial logic in which update is an operator in the object language.

We shall therefore choose update as the notion of change. The *KM* postulates do not prescribe any particular update operator; they characterize a class of acceptable operators. As Katsuno and Mendelzon show, an operator satisfies the postulates if and only if it has the following behavior. For each model \mathcal{M} of the theory to be changed, find the set of models of the sentence to be inserted that are “closest” to \mathcal{M} . The theory that describes all models obtained in this way is the result of the change operation. Choosing an update operator then reduces to choosing a notion of closeness of models. In this paper, we adopt Winslett’s *possible models approach* [Win89]. Loosely speaking, a relational database D_1 is closer than another database D_2 to the initial database D under the Winslett ordering if every tuple that must be inserted or deleted into D to make it identical with D_1 must also be inserted or deleted to make D identical with D_2 .

Note that we are talking about comparing databases rather than theories, equating databases with models of a theory. This is in fact our data model: we define a database to be a finite relational structure, and a knowledgebase to be a finite set of databases on the same schema. We follow the *closed world assumption*: only the facts that are explicitly stored are true in a database [Rei78].

Having settled on a data model and a notion of update, we propose a language that will allow both queries and updates to be expressed uniformly. In fact, in our language there is no formal distinction between queries and updates; they are both regarded as *transformations*. The language

contains an operator that “inserts” arbitrary first-order sentences into a knowledgebase, producing a new knowledgebase.

EXAMPLE 1.2. Suppose that we have in our knowledgebase a relation containing all the direct flight paths from cities to cities and would like to ask the following query “which cities are reachably directly or indirectly from Toronto via Air Canada?”. This query is expressed by inserting into the knowledgebase a sentence that defines a new relation containing exactly these cities, i.e., the sentence that defines the transitive closure of the given relation. (In the first example of Section 3 we elaborate further on the transitive closure query.) For expressing the update “delete flight AC902” it is enough to insert into the knowledgebase the sentence that denies the existence of this flight.

Note that, for example, positive existential relational calculus formulas are already expressive enough to formulate updates that can have multiple results. As observed in [AbG85], updates with multiple results are the source of indefiniteness in databases. Considerable expressive power is achieved by the combination of first-order logic and the minimization operator implicit in the *KM* notion of update and the Winslett order. It turns out that, for example, all *fixpoint queries* [CH82] are expressible in our transformation language. It is well-known that “inserting” a *datalog* program into an “extensional database” produces a unique minimal model, which model also can be characterized as a least fixpoint of the program. In case a formula has the syntax of a *datalog* program, or, more generally, is monotone, our update operator also produces that least fixpoint.

The major results of the paper are the following: (1) definition of a simple and versatile first-order knowledgebase update language (2) proof that the basic update operator in this language satisfies the Katsuno–Mendelzon postulates for updates (3) an analysis of the computational complexity and expressive power of the knowledgebase update language.

In Section 2 of this paper we lay the foundation of knowledgebase transformations. In Section 3 some examples of transformations are exhibited. The computational complexity of transformations is the subject of Section 4, and expressive power is discussed in Section 5.

2. THE FRAMEWORK

As a notational convenience, the symbol ω denotes the set of all natural numbers, while the symbol \oplus denotes the symmetric set difference operation, that is, $A \oplus B = (A \setminus B) \cup (B \setminus A)$.

Consider a first-order function free language \mathcal{L} built from the following components: A set $A = \{a_i; i \in \omega\}$ of *domain elements*, a set $X = \{x_i; i \in \omega\}$ of *variables*, a set $R = \{R_i; i \in \omega\}$ of *relation symbols*, \wedge (and), \neg (negation),

\exists (existential quantifier), $=$ (equality), and the parenthesis symbols.

With each relation symbol $R_i \in R$ we associate the *arity* $\alpha(i)$. A k -ary term is a tuple with k components, each in $A \cup X$. An *atomic formula* is an expression of the form $R_i(x)$ where R_i is in R and x is an $\alpha(i)$ -ary term, or an expression of the form $x_i = x_j$, or an expression of the form $x_i = a_j$, where $\{x_i, x_j\} \subseteq X$, and $a_j \in A$.

The set of all *well formed formulas* of \mathcal{L} is defined in the usual way, and it is denoted Φ' . The subset of *sentences* in Φ' is denoted Φ . If ϕ is a formula where variable x_i occurs free, then $\phi(x_i/a_j)$ denotes the formula ϕ with each free occurrence of x_i substituted by a_j .

A database db is a sequence $\langle r_{i_1}, \dots, r_{i_n} \rangle$ of relations, where each r_{i_j} is a finite subset of $A^{\alpha(i_j)}$. Then the schema of db is $\sigma(db) = \{R_{i_1}, \dots, R_{i_n}\}$.

For $\phi \in \Phi$, define the schema $\sigma(\phi)$ to be the set of all relation symbols appearing in ϕ .

The set of all databases is denoted \mathcal{DB} . By \mathcal{DB}_s we mean the set of all databases on schema s . Furthermore, if B is a subset of the domain A , then \mathcal{DB}_s^B denotes the set of all databases on schema s containing only values in B .

Let db_1 and db_2 be databases. Then we say that $\sigma(db_2)$ *dominates* $\sigma(db_1)$, if $\sigma(db_1)$ is a subset of $\sigma(db_2)$.

The following is a key definition in this paper. It defines a partial order relation \leq with respect to a given database. Intuitively, this relation is used to rank the desirability of including a database withing the updated knowledgebase.

DEFINITION 2.1. Let $db_1 = \langle s_{i_1}, \dots, s_{i_n} \rangle$ and $db_2 = \langle u_{i_1}, \dots, u_{i_n} \rangle$ be databases, where $\sigma(db_1) = \sigma(db_2)$, and let db be such that $\sigma(db_1)$ dominates $\sigma(db)$.

Then define a relation \leq_{db} over $\mathcal{DB}_{\sigma(db_1)}$, such that $db_1 \leq_{db} db_2$ if and only if either

$$s_{i_j} \oplus r_{i_j} \subseteq u_{i_j} \oplus r_{i_j}, \quad (1)$$

for all r_{i_j} , s_{i_j} , and u_{i_j} , whose schemas occur in all three databases, or

$$s_{i_j} \oplus r_{i_j} = u_{i_j} \oplus r_{i_j}, \quad (2)$$

for all r_{i_j} , s_{i_j} , and u_{i_j} , whose schemas occur in all three databases, and

$$s_{i_k} \oplus \emptyset \subseteq u_{i_k} \oplus \emptyset, \quad (3)$$

hold for the rest of the relations s_{i_k} and u_{i_k} in db_1 and db_2 .

We give an example of partial order. Let $db_1 = \langle \{R(a_1 a_2), S(a_1 a_4)\} \rangle$ and $db_2 = \langle \{R(a_1 a_2), S(a_1 a_4), S(a_2 a_3)\} \rangle$ and $db = \langle \{R(a_1 a_2)\} \rangle$.¹ Here $\sigma(db_1) = \sigma(db_2) = \{R, S\}$

¹ In this example, we indicated which tuple belongs to which relation by explicitly writing out "R" and "S", in some examples later when the schema is a singleton we will drop the relation symbol.

and $\sigma(db) = \{R\}$. Since all three relations agree in R , and S in db_1 is a strict subset of S in db_2 , we have that $db_1 \leq_{db} db_2$.

From this example, it can be easily seen that \leq_{db} is a partial order.

This partial order compares the databases in $\mathcal{DB}_{\sigma(db_1)}$ with respect to their *closeness* to the database db . If $\sigma(db) = \sigma(db_1) = \sigma(db_2)$, then we have $db_1 \leq_{db} db_2$ if and only if the symmetric difference between db_1 and db is included in the symmetric difference between db_2 and db , where the symmetric difference is taken componentwise. This corresponds to the way interpretations are compared in Winslett's possible models approach [Win89]. If the schemas of db_1 and db_2 are proper supersets of db , the comparison will proceed in two stages. First, we try to keep the relations in db invariant. Since $r \oplus r = \emptyset$, for any relation r , condition (1) will guarantee that the databases where the relations in db are invariant will be closer to db than other databases. These other databases will be ordered in two stages: First, smaller changes to the relations in the db are favored (condition (1)). If two databases have the same changes to these relations (condition (2)), then the other relations are compared *w.r.t.* the empty set, since these relations are not present in db (condition (3)). Since $r \oplus \emptyset = r$, for any relation r , databases with smaller relations will be favored in the order.

A *knowledgebase* kb is a finite set of db 's with the same schema. This schema is also the schema of the knowledgebase. The set of all knowledgebases is denoted \mathcal{KB} .

The *interpretation* of a sentence $\phi \in \Phi$ *w.r.t.* a database db is a relation \models on $\mathcal{DB} \times \Phi$ defined for db and ϕ if and only if $\sigma(db)$ dominates $\sigma(\phi)$, in which case the recursive definition is

$$db \models (a_i = a_j) \quad \text{if} \quad i = j \quad (4)$$

$$db \models R_i(x) \quad \text{iff} \quad x \in r_i \quad (5)$$

$$db \models (\phi \wedge \psi) \quad \text{iff} \quad db \models \phi \quad \text{and} \quad db \models \psi \quad (6)$$

$$db \models (\neg \phi) \quad \text{iff} \quad \text{not} \quad db \models \phi \quad (7)$$

$$db \models (\exists x_i \phi) \quad \text{iff} \quad db \models \phi(x_i/a_j) \quad \text{for some} \quad a_j \in A \quad (8)$$

By $\llbracket \phi \rrbracket$ we mean the set of all databases such that $\models (db, \phi)$ is true. We call $\llbracket \phi \rrbracket$ the models of ϕ . We say that ϕ *finitely implies* ψ , if $\llbracket \phi \rrbracket \subseteq \llbracket \psi \rrbracket$.

If s is a schema and B is a subset of the domain A , then $\llbracket \phi \rrbracket_s^B$ denotes the set $\llbracket \phi \rrbracket \cap \mathcal{DB}_s^B$.

Let $DB \subseteq \mathcal{DB}$, and $\{db, db_1\} \subseteq \mathcal{DB}$. Then we say that db_1 is \leq_{db} -*minimal* in DB , if db_1 is in DB , and if $db_2 \in DB$ and $db_2 \leq_{db} db_1$ entails $db_2 = db_1$.

Now consider the function $\mu: \Phi \times \mathcal{DB} \rightarrow \mathcal{KB}$, defined as

$$\mu(\phi, db) = \{db' \in \mathcal{DB}_s^B : db' \text{ is } \leq_{db}\text{-minimal in } \llbracket \phi \rrbracket_s^B\}, \quad (9)$$

where B is the smallest subset of the domain A , such that B contains all values that appear in db and ϕ , and \mathfrak{s} is the schema $\sigma(db) \cup \sigma(\phi)$.

The function μ thus picks the models of ϕ that are closest to db among the databases that have no other relations than those in db and those mentioned in the sentence ϕ , and no other values than those appearing in db or in ϕ .

Next, consider the (partial) transformation functions $\tau: \Phi \times \mathcal{KB} \rightarrow \mathcal{KB}$, $\sqcap: \mathcal{KB} \rightarrow \mathcal{KB}$, $\sqcup: \mathcal{KB} \rightarrow \mathcal{KB}$, and $\pi_{i_1, \dots, i_k}: \mathcal{KB} \rightarrow \mathcal{KB}$, where

$$\tau_\phi(kb) = \bigcup_{db \in kb} \mu(\phi, db). \quad (10)$$

and $\sqcap(kb)$ is the componentwise intersection of the databases in kb , i.e. the glb of kb w.r.t. to the Cartesian generalization of subset inclusion. Likewise, $\sqcup(kb)$ is the componentwise union of lub . As an example, let $kb = \{ \langle \{a_1 a_2, a_1 a_4\} \rangle, \langle \{a_1 a_4, a_2 a_3\} \rangle \}$. Here the knowledgebase contains two databases with the same schema. The value of $\sqcap(kb)$ is $\{ \langle \{a_1 a_4\} \rangle \}$ and the value of $\sqcup(kb)$ is $\{ \langle \{a_1 a_2, a_2 a_3, a_1 a_4\} \rangle \}$.

A function π maps a kb to the kb that is obtained by projecting each db in the input to the components whose indices appear in the subscript of π .

The function τ can be seen as an update function, in that $\tau_\phi(kb)$ “inserts” ϕ into kb , producing a new kb . In the space example in Section 1, the knowledgebase T would be $kb = \{ \langle \{v\} \rangle, \langle \{w\} \rangle \}$, where v is a tuple corresponding to the proposition “ V has landed,” and likewise for w . Let these tuples be over schema R_1 . When we learn that V has landed we perform the update

$$\tau_{R_1(v)}(kb) = \{ \langle \{v\} \rangle, \langle \{v, w\} \rangle \}.$$

Note. We do not need to express the traditional projection operator, because it can be expressed by the above more general projection and the transformation operators. For example, suppose that we have a knowledgebase with schema $\{R\}$ where R is a binary relation symbol and that the knowledgebase contains a single database in it. Suppose that we want to express the regular projection operation onto the first column of R . This can be accomplished by inserting the sentence.

$$\pi_{R.1} \tau_{R_1(x) \leftarrow R(x, y)}(kb).$$

The output relation R_1 will be the projection as desired. It similarly can be checked that the standard selection operation is also expressible in our transformation language. In general, it turns out that the following properties, corresponding to the *KM*-postulates [KM91a] for update, hold.

THEOREM 2.1. *For all schema-wise appropriate db , kb , kb_1 , and kb_2 :*

- (i) $\tau_\phi(kb) \subseteq \llbracket \phi \rrbracket$
- (ii) *If $kb \subseteq \llbracket \phi \rrbracket$, then $\tau_\phi(kb) = kb$*
- (iii) *If $kb \neq \emptyset$ and $\llbracket \phi \rrbracket_{\mathfrak{s}}^B \neq \emptyset$, then $\tau_\phi(kb) \neq \emptyset$*
- (iv) *If $\llbracket \phi \rrbracket = \llbracket \psi \rrbracket$, then $\tau_\phi(kb) = \tau_\psi(kb)$*
- (v) $\tau_\phi(kb) \cap \llbracket \psi \rrbracket \subseteq \tau_{\phi \wedge \psi}(kb)$
- (vi) *If $\tau_\phi(kb) \subseteq \llbracket \psi \rrbracket$, and $\tau_\psi(kb) \subseteq \llbracket \phi \rrbracket$, then $\tau_\phi(kb) = \tau_\psi(kb)$*
- (vii) $\tau_\phi(\{db\}) \cap \tau_\psi(\{db\}) \subseteq \tau_{\phi \vee \psi}(\{db\})$
- (viii) $\tau_\phi(kb_1 \cup kb_2) = \tau_\phi(kb_1) \cup \tau_\phi(kb_2)$

Proof. (i) Let $db \in \tau_\phi(kb)$. From (9) it follows that $db \in \llbracket \phi \rrbracket_{\mathfrak{s}}^B$. Since $\llbracket \phi \rrbracket_{\mathfrak{s}}^B \subseteq \llbracket \phi \rrbracket$, the claim follows.

(ii) Let $db' \in \tau_\phi(kb)$. Then there is a $db \in kb$, such that db' is \leq_{db} -minimal in $\llbracket \phi \rrbracket_{\mathfrak{s}}^B$. Since $kb \subseteq \llbracket \phi \rrbracket$, we have $db \in \llbracket \phi \rrbracket_{\mathfrak{s}}^B$. Now db is the unique \leq_{db} -minimal element in $\llbracket \phi \rrbracket_{\mathfrak{s}}^B$. Thus $db' = db$, and consequently $\tau_\phi(kb) \subseteq kb$.

For inclusion in the other direction, let $db \in kb$. Since $kb \subseteq \llbracket \phi \rrbracket$, db is the unique \leq_{db} -minimal element in $\llbracket \phi \rrbracket_{\mathfrak{s}}^B$. Therefore $db \in \tau_\phi(kb)$.

(iii), (iv), and (viii) These are immediate consequences of definitions (9) and (10).

(v) Let $db' \in \tau_\phi(kb) \cap \llbracket \psi \rrbracket \neq \emptyset$. Then there is a $db \in kb$, such that $db' \in \mu(\phi, db)$, and $db' \in \llbracket \phi \wedge \psi \rrbracket_{\sigma(db) \cup \sigma(\phi)}^B$, where B is the set of values appearing in db or ϕ . Suppose now towards a contradiction that db' is not in $\mu(\phi \wedge \psi, db)$. Then there must be some database, say db'' , such that $db'' \leq_{db} db'$, $db'' \neq db'$, and $db'' \in \llbracket \phi \wedge \psi \rrbracket_{\sigma(db) \cup \sigma(\phi)}^{B'}$. Here B' is the set of values appearing in db , ϕ , or ψ . It now follows that db'' also is in $\llbracket \phi \rrbracket_{\sigma(db) \cup \sigma(\phi)}^B$. Thus we have a contradiction to the fact that $db' \in \mu(\phi, db)$.

(vi) We show that, given the assumptions, $\tau_\phi(kb) \subseteq \tau_\psi(kb)$. Let $db' \in \tau_\phi(kb)$. Then there is a $db \in kb$, such that $db' \in \mu(\phi, db)$. We claim that $db' \in \mu(\psi, db)$. Suppose the contrary. We can assume w.l.o.g. that $\sigma(\phi) = \sigma(\psi)$, and that the values appearing in ϕ and ψ are the same. Let B be the set of values in db and ϕ . Since $db' \in \llbracket \psi \rrbracket_{\sigma(db) \cup \sigma(\psi)}^B$, the set $\mu(\psi, db)$ must be nonempty. Let therefore $db'' \in \mu(\psi, db)$. Then it must be that $db'' \leq_{db} db'$, and $db'' \neq db'$. But this is not possible, since $db' \in \llbracket \phi \rrbracket_{\sigma(db) \cup \sigma(\phi)}^B$, thus yielding a contradiction to the fact that $db' \in \mu(\phi, db)$. The argument for inclusion in the other direction is symmetrical.

(vii) Let $db' \in \mu(\phi, db) \cap \mu(\psi, db)$. Again, can assume w.l.o.g. that $\sigma(\phi) = \sigma(\psi)$. Let B be the set of values appearing in db or σ , and B' the set of those appearing in db or ψ . From the assumption it follows that $\mu(\phi \vee \psi, db) \neq \emptyset$. If $db' \notin \mu(\phi \vee \psi, db)$, there must be a $db'' \in \mu(\phi \vee \psi, db)$, such that $db'' \leq_{db} db'$, and $db'' \neq db'$. It now follows that db'' is in $\llbracket \phi \rrbracket_{\sigma(db) \cup \sigma(\phi)}^B$, or in $\llbracket \psi \rrbracket_{\sigma(db) \cup \sigma(\psi)}^{B'}$. In the first case we have a

contradiction to the fact that $db' \in \mu(\phi, db)$, and in the second case to the fact that $db' \in \mu(\psi, db)$. ■

The next lemma illustrates an elementary property of the transformation language. It shows that update does not commute with glb and lub.

LEMMA 2.1. *There are knowledgebases and sentences such that $\sqcap(\tau_\phi(kb)) \neq \tau_\phi(\sqcap(kb))$, and $\sqcup(\tau_\phi(kb)) \neq \tau_\phi(\sqcup(kb))$.*

Proof. Let $kb = \{\langle \{a_1 a_2 a_3\} \rangle, \langle \{a_1 a_2 a_4\} \rangle\}$, that is, two databases, each with a single tuple over schema, say, R_1 . Then the value of

$$\sqcap(\tau_{\forall_{x_1 x_2} R_1 x_1 a_2 x_2 \rightarrow R_2 x_1}(kb))$$

is $\{\langle \emptyset, \{a_1\} \rangle\}$, where the second relation is on schema R_2 . On the other hand, commuting \sqcap and τ produces $\{\langle \emptyset, \emptyset \rangle\}$.

For the second part of the lemma, let $kb = \{\langle \{a_1 a_2\} \rangle, \langle \{a_2 a_3\} \rangle\}$, with schema R_3 . Then the value of

$$\tau_{\forall_{x_1 x_2 x_3} (R_3 x_1 x_3) \vee (R_3 x_1 x_2 \wedge R_3 x_2 x_3) \rightarrow R_4 x_1 x_3} \left(\sqcup(kb) \right)$$

is $\{\langle \{a_1 a_2, a_2 a_3\}, \{a_1 a_2, a_2 a_3, a_1 a_3\} \rangle\}$, while commuting the operators results in $\{\langle \{a_1 a_2, a_2 a_3\}, \{a_1 a_2, a_2 a_3\} \rangle\}$. ■

By composing the transformation functions in the obvious way, and by using schemas as parameters, *transformation expressions* can be formed. For example, $\pi_1(\tau_\psi(\sqcap(\tau_\phi(R_1, R_2))))$ is a transformation expression. The *value* of this expression, when applied to a knowledgebase, say $\{\langle r_1, r_2 \rangle, \langle s_1, s_2 \rangle\}$, is the value of the transformation obtained by substituting the parameters by the knowledgebase, that is $\pi_1(\tau_\psi(\sqcap(\tau_\phi(\{\langle r_1, r_2 \rangle, \langle s_1, s_2 \rangle\})))$. Transformation expressions will be denoted by θ, θ', \dots , while Θ denotes the set of all transformation expressions. In the sequel we shall leave out extra parenthesis symbols whenever there is no risk of confusion.

2.1. Comparison with Related Work

At this point it is possible to compare our approach with some previous work on update languages.

Abiteboul and Vianu [AV87, AV88] define a class of non-deterministic transformations on databases that they call *updates*. This class is similar to our transformations in that it includes queries and modifications of the database state as special cases. They define an update as a relation between instances of a fixed schema s and another fixed schema t that is recursively enumerable and *C-generic* for some finite C . (Recall that a binary relation $r \subset A \times B$ is *C-generic*, for C a subset of $A \cup B$, if for every bijection ρ over $A \cup B$ which is the identity on C , $(i, j) \in r$ if and only if $(\rho(i), \rho(j)) \in r$.) If we restrict our attention to the case

where the input knowledgebases are singletons, i.e. databases, it is clear that the transformations defined by Θ expressions are updates in the sense of Abiteboul and Vianu. In fact, they are within the subclass that they call *finitely nondeterministic updates*, those in which the set of all output databases related to each input database is finite. They also consider *deterministic updates*, in which the relation is a function. In Section 5, we consider a class of Θ expressions that falls within this subclass: those expressible by a transformation on the form $(\pi b \tau \cup \pi \tau)^*$, where each b is one of \sqcap or \sqcup .

The work of Fagin *et al.* [FUV83, FKUV86] considers updates of logical databases, where the database is described by a set of sentences. The essential idea in [FUV83] is to consider all maximal subsets of the set of sentences in the database that is consistent with the sentence that is inserted. Although this definition seems intuitive, we do not follow this because it does not satisfy the Katsuno–Mendelzon postulates for updates. The essential problem is that it does not satisfy the principle of the irrelevance of syntax, i.e., the results of the update should not depend on the exact syntax of the set of sentences in the knowledgebase, but only on their semantics. This is in fact one of the harder postulates to satisfy and in [KM91a, KM91b] it is shown that several other update operator proposals also do not satisfy this principle. Another difference between the update operator in [FUV83] and in this paper is that in the former priorities, that is integer numbers, are assigned to sentences and these are also taken into account in the definition of maximum consistent subset. Furthermore, [FUV83] considered inserting only a single sentence into the database. This limitation was removed by [FKUV86] that defined the flock semantics for updates that allows insertion of a group of sentences. Our update operator also allows the simultaneous insertion of a group of sentences by treating each group of sentences as the conjunction of the sentences.

It is well-known that if the Horn clause form of logic programs is relaxed, then there might be several least fixpoints of a program. In this case our update operator produces all least fixpoints *w.r.t.* a generalization of the usual subset inclusion into the partial order based on Boolean sum. This is in contrast to the more common approach to designate one of the models, or some other relational structure, as the “intended model” of the program. As is demonstrated in [IN88] such intended models might force the programmer to express his or her intentions in a cumbersome way. We do however note that the *iterative fixpoint* [ABW88] of a stratified program can be obtained in our language by sequentially updating the database with the strata of the program in their hierarchical order.

It is also interesting to note that *hypothetical queries* [Bon88, Gab85] and *queries on recursively indefinite databases* [Mey90] can be expressed through updates. The

connection between hypothetical queries and updates is explored in [GM95].

3. SAMPLE TRANSFORMATION

In this section we present seven example transformations. First we show that the common queries of transitive closure (Example 1) and parity (Example 6) can be expressed. We also show that the robots query described in the introduction can also be expressed (Example 4). The remaining examples express increasingly harder queries on graphs. In particular transformations for transitive reductions (Example 2), edges belonging to every transitive reduction (Example 3), monochromatic triangle (Example 5), and maximal clique (Example 7) are given. Since the harder graph queries build on the results of the earlier ones, the examples used here also illustrate the high degree of modularity inherent in our transformation language. In the presentation, the examples are ordered in increasing level of difficulty.

EXAMPLE 1. Let r be a relation such that $\sigma(r) = R_1$, and let ϕ be the sentence

$$\forall_{x_1, x_2, x_3}: (R_2 x_1 x_2 \wedge R_1 x_2 x_3) \vee R_1 x_1 x_3 \rightarrow R_2 x_1 x_3.$$

Explanation. $\pi_2 \tau_\phi(\{\langle r \rangle\}) = \{\langle s \rangle\}$, where s is the *transitive closure* of r , and $\sigma(s) = R_2$. To see that this is indeed the case, note that by definition (10), the databases returned by τ_ϕ are models of sentence ϕ . For a database to be a model, it has to satisfy both of the conditions $\forall_{x_1, x_2, x_3} R_1 x_1 x_3 \rightarrow R_2 x_1 x_3$ and $\forall_{x_1, x_2, x_3} (R_2 x_1 x_2 \wedge R_1 x_2 x_3) \rightarrow R_2 x_1 x_3$. By the first condition, s must contain r . By the second condition, for any path in r , that is, any set of tuples $\{a_1 a_2, \dots, a_{k-1} a_k\} \subseteq r$, there must be an edge $a_1 a_k \in s$. This can be proven by induction. Hence, the relation s must contain also the transitive closure of r . By definition (9), the relation that results from applying the transformation must be minimal. In addition, the definition of minimality ensures that the argument relation r is not altered while an s can be found such that $\langle r, s \rangle$ is a model of ϕ . Clearly, for any r we can always find a transitive closure s , hence r will never need to be changed according to the minimality condition. Therefore, after the projection operation, the result will be exactly the transitive closure of r .

EXAMPLE 2. To transform a directed graph r_1 into the set of its *transitive reductions*, let ψ be the following sentence:

$$\forall_{x_1, x_2}: R_2 x_1 x_2 \rightarrow R_1 x_1 x_2.$$

Also, let χ be the conjunction of sentences

$$\forall_{x_1, x_2, x_3}: (R_3 x_1 x_2 \wedge R_1 x_2 x_3) \vee R_1 x_1 x_3 \leftrightarrow R_3 x_1 x_3,$$

$$\forall_{x_1, x_2, x_3}: (R_3 x_1 x_2 \wedge R_2 x_1 x_3) \vee R_2 x_1 x_3 \leftrightarrow R_3 x_1 x_3.$$

Explanation. $\pi_2 \tau_{\psi \wedge \chi}(\{\langle r_1 \rangle\}) = \{\langle r_{2_1} \rangle, \dots, \langle r_{2_k} \rangle\}$, where each r_{2_i} is a transitive reduct of r_1 . Recall that a binary relation r_2 is a transitive reduction of r_1 if and only if r_2 is an antitransitive subset of r_1 , and the transitive closure of r_2 is the same as the transitive closure of r_1 . (Here antitransitivity means that for any $a_1 a_3$ in r_2 , there is no a_2 such that both $a_1 a_2$ and $a_2 a_3$ are also in r_2 .) Note also that by definition (9), the relation r_1 does not change if suitable r_2 and r_3 can be found. This will indeed be the case.

At first we check that r_2 satisfies the second requirement to be a transitive reduction of r_1 . By the first part of sentence χ , the relation r_3 is the transitive closure of r_1 , because it is just like in Example 1, except for the bidirectionality of the implication. By sentence ψ , r_2 must be a subset of r_1 , and by the second part of sentence χ , this subset must have the same transitive closure as r_1 has. Here we need the bidirectionality.

Second, for r_2 to be a transitive reduction of r_1 , it also has to be antitransitive. This condition is satisfied by the minimality requirement. For suppose that r_2 is not antitransitive. Then r_2 must contain a certain subset, say $\{a_1 a_2, a_2 a_3, a_1 a_3\}$. Clearly, the relation $r_2 \setminus \{a_1 a_3\}$ has the same transitive closure as r_2 has, but it has fewer tuples, and will hence by μ be preferred over r_2 .

Since the two conditions are satisfied, after operation π_2 the knowledgebase will indeed contain the set of transitive reducts of the original graph.

EXAMPLE 3. Suppose now that we would like to know whether a certain set of edges belongs to every transitive reduction of a graph. This query can be expressed in the language of *recursively indefinite database* [Mey90]. The query can also be formulated as a transformation expression. Suppose that the relation r_3 describes the set of edges in question. Let the sentence ζ be

$$\forall_{x_1, x_2}: (R_3 x_1 x_2 \rightarrow R_2 x_1 x_2) \rightarrow R_4.$$

Explanation. The transformation $\pi_4 \tau_\zeta \theta(\{\langle r_1, r_3 \rangle\})$, where θ is $\pi_{2,3} \sqcap \tau_{\psi \wedge \chi}(\{\langle r_1, r_3 \rangle\})$ will yield one zeroary relation r_4 that will contain the empty tuple if and only if $r_3 \subseteq r_2$ where r_2 stores the set of edges that belong to all transitive reductions of graph r_1 , and r_3 is the given set of edges.

To see this, note that $\theta(\{\langle r_1, r_3 \rangle\}) = \{\langle r_2, r_3 \rangle\}$ is as in the previous example, except that r_3 is present and preserved unchanged by θ , and we take \sqcap the common set of edges in r_2 .

In the τ_ζ operation we added to our sentence ψ an implication for relation r_4 . Here the minimality requirement assures that r_4 will be empty if and only if r_3 is not a subset of r_2 .

EXAMPLE 4. Transformation expressions can also describe hypothetical, or *subjective* queries. Recall the space

example from Section 2. Let the knowledgebase be $kb = \{\langle \{v\} \rangle, \langle \{w\} \rangle\}$, and consider the query “if V had landed, would W be necessarily still orbiting?”. The answer to this query would be “yes” if and only if the resulting singleton knowledgebase of the transformation

$$\sqcup \tau_{R_1(v)}(kb).$$

does not contain w . Since $\sqcup \tau_{R_1(v)}(kb) = \{\langle \{v, w\} \rangle\}$ this is not the case.

Note. The above example expresses a type of hypothetical queries called *counterfactual* queries. A counterfactual query, denoted as $A > B$, has two parts an antecedent (A) and a consequent (B), and the antecedent is known to be false. A counterfactual query is true whenever “if the antecedent were true then the consequent would be also true”. It is possible to generalize from this example to any right-nested $(A > (B > C)) \dots$ counterfactual query. These can be expressed by nested transformations $\tau_A(\tau_B(\tau_C)) \dots$.

EXAMPLE 5. Now consider the *monochromatic triangle* problem, that is, the problem of deciding whether an undirected graph r_1 has a partition into two graphs r_2 and r_3 such that both r_2 and r_3 are antitransitive.

Let v be the sentence

$$\forall_{x_1 x_2} : R_1 x_1 x_2 \rightarrow R_2 x_1 x_2 \vee R_3 x_1 x_2.$$

Let ρ be the conjunction of sentences

$$\forall_{x_1 x_2 x_3} : R_2 x_1 x_2 \wedge R_2 x_2 x_3 \rightarrow \neg R_2 x_1 x_3,$$

$$\forall_{x_1 x_2 x_3} : R_3 x_1 x_2 \wedge R_3 x_2 x_3 \rightarrow \neg R_3 x_1 x_3,$$

$$\forall_{x_1 x_2} : R_1 x_1 x_2 \leftrightarrow R_1 x_2 x_1,$$

$$\forall_{x_1 x_2} : R_2 x_1 x_2 \leftrightarrow R_2 x_2 x_1,$$

$$\forall_{x_1 x_2} : R_3 x_1 x_2 \leftrightarrow R_3 x_2 x_1.$$

Let ζ' be the sentence $R_6 \leftrightarrow \forall_{x_1 x_2} \neg R_5 x_1 x_2$, and let the operation τ_η denote copying the relation r_1 into a relation r_4 , while τ_ϵ is denoting assigning the value of $r_4 \setminus r_1$ into relation r_5 . (From looking at the previous examples, the last two are easily expressible as a transformation.)

Explanation. The result of the transformation $\sqcup \tau_{\zeta'} \theta$, where θ is the subexpression $\pi_5 \tau_\epsilon \tau_\nu \wedge \rho \tau_\eta(R_1)$, has in r_6 the empty tuple if and only if r_1 has the described partition.

Consider at first the sentence v . It formalizes the fact that r_2 and r_3 form a partition of r_1 . The disjointness of r_2 and r_3 is enforced by equation (3) in the definition of the τ -operation. That is because if we had $a_i \in r_2 \cap r_3$, then by taking $r_2 \setminus \{a_i\}$ instead of r_2 and the same r_3 , we could also

satisfy the sentence v . The choice between these two databases depends on equation (3) because the relation r_2 is not an input relation. Equation (3) clearly prefers the second database.

Next see that the sentence ρ says that r_2 and r_3 are antitransitive, and that each of the relations r_1, r_2, r_3 are symmetric.

After the second τ operation we have all possible partitions in the knowledgebase, but we may have some undesirable partitions, that is, partitions that change the initial relation r_1 . Since we have a copy of the initial relation in r_4 , we can check whether there are any partitions that are desirable. Therefore, after θ , a required partition exists if and only if r_5 is empty in some of the databases.

The transformation $\sqcup \tau_{\zeta'}$ checks exactly if r_5 is empty in some of the databases in $\theta(\{\langle r_1 \rangle\})$. If r_5 is indeed empty in some of the databases, then r_6 will have in it the empty tuple. Otherwise r_6 will be the empty relation by the minimization requirement. Hence we see that the transformation expression is a yes or no query corresponding to the monochromatic triangle problem.

EXAMPLE 6. The *parity* problem is, does a given unary relation r_1 have an even number of elements.

Let v' be the sentence

$$\forall_{x_1} : R_1 x_1 \rightarrow (R_2 x_1 \vee R_3 x_1).$$

Let ϕ be the sentence

$$\forall_{x_1 x_2} : (R_2 x_1 \wedge R_3 x_2) \rightarrow R_4 x_1 x_2.$$

Let ζ be the conjunction of sentences

$$\forall_{x_1 x_2 x_3} : (R_4 x_1 x_2 \wedge R_4 x_1 x_3) \rightarrow x_2 = x_3,$$

$$\forall_{x_1 x_2 x_3} : (R_4 x_2 x_1 \wedge R_4 x_3 x_1) \rightarrow x_2 = x_3.$$

Let ϱ be the sentence

$$\forall_{x_1 x_2} : (R_4 x_1 x_2 \vee R_4 x_2 x_1) \rightarrow R_5 x_1.$$

Let τ_i denote the transformation that assigns $r_1 \setminus r_5$ to r_6 . Let θ be the expression $\pi_{1,5} \tau_\varrho \tau_\zeta \tau_\phi \tau_{v'}(R_1)$.

Explanation. The transformation $\pi_6 \tau_i \theta(\{\langle r_1 \rangle\})$ results in a knowledgebase that has a database in which the relation r_6 is empty if and only if the parity of r_1 is even.

Note that r_1 has an even number of elements if and only if r_1 can be partitioned into two unary relations r_2 and r_3 of the same cardinality. This serves as the basic intuition behind the transformation expression. In other words, we have here an expression that results in a knowledgebase containing a single database that contains the relation r_6 as empty if and only if r_1 has the desired partition.

Clearly, the sentence v' is similar to v in Example 5 and says that r_2 and r_3 form a partition. Now r_2 and r_3 have an equal number of elements if and only if there is a function from r_2 to r_3 that is bijective. In our example, the relation r_4 is such a bijection.

The knowledgebase after the insertion of v' will contain a set of databases each of which specifies a partition of r_1 into an r_2 and r_3 . Next the insertion of φ into the knowledgebase will result in the addition of an r_4 that is the Cartesian product of r_2 and r_3 within each of the databases. The insertion of ζ will eliminate all but those databases where r_4 is a bijection of r_2 and r_3 .

The insertion of ϱ adds a new relation r_5 that will contain all the elements occurring in r_4 (either as first or second argument) in each database. We claim that r_5 will be equal to r_1 in a database if and only if r_1 has an even number of elements.

To prove if: if r_1 has an even number of elements, then there is clearly a partition into r_2 and r_3 that have the same number of elements and to there an r_4 that is a bijection. The first arguments of r_4 will be equal to the elements of r_2 and the second arguments of r_4 will be equal to r_3 , hence the union of these which will be output as r_5 must be the same as r_1 .

To prove only if: if there is no database with r_5 equal to r_1 , then in any database there must be some item a in r_1 that does not occur as either the first or the second argument of r_4 after the insertion of ζ . We know that a must be in either r_2 or r_3 . Let us suppose without loss of generality that a is in r_2 . Then since r_2 and r_3 is a partition, it cannot belong to r_3 (partitions are disjoint and the disjointness is enforced by the minimality condition as in Example 5). Since a belongs to r_2 and it is not paired by any element of r_3 there must be an odd number of elements. (Note that r_3 cannot also have an element b that is not paired with any element in r_2 because that would contradict the minimality condition, i.e., from the Cartesian product of r_2 and r_3 the relation $r_4 \cup (ab)$ would be closer than the relation r_4 obtained after insertion of ζ .) Hence r_1 must have an odd number of elements.

Therefore it is clearly enough to check that in the knowledgebase that results after performing θ one of the databases contains an r_5 that is equal to r_1 . We can use here the transformation τ , similarly to the τ_e transformation in Example 5. Then r_6 will be the empty relation in one of the databases if and only if the initial r_1 had an even number of elements.

EXAMPLE 7. The *maximal clique* problem asks for a graph whether the largest clique or maximal complete subgraph has exactly size k .

Let r_1 be the set of edges of a graph. Let r_2 be any set with exactly k elements and r_3 be any set with exactly $k+1$ elements. Let ϕ be the following conjunction of sentences:

$$\forall_{x_1} \exists_{x_2} : R_2 x_1 \rightarrow R_5 x_1 x_2,$$

$$\forall_{x_1} \exists_{x_2} : R_4 x_1 \rightarrow R_5 x_2 x_1,$$

$$\forall_{x_1 x_2 x_3} : R_5 x_2 x_1 \wedge R_5 x_3 x_1 \rightarrow x_2 = x_3,$$

$$\forall_{x_1 x_2 x_3} : R_5 x_1 x_2 \wedge R_5 x_1 x_3 \rightarrow x_2 = x_3,$$

$$\forall_{x_1 x_2} : R_4 x_1 \wedge R_4 x_2 \wedge x_1 \neq x_2 \rightarrow R_1 x_1 x_2.$$

Explanation. Transformation τ_ϕ can be used to check whether the graph has a clique of size k .

If the graph has a clique of size k , then the vertices of one such clique will be placed in the unary relation r_4 . To see that, note that besides r_4 , an r_5 relation has to be found. Since r_5 is a new relation, it must be a minimal-size relation. Also by the first four lines, r_5 is a bijection from r_2 to r_4 . Hence the size of r_2 and r_4 will be the same. Hence the size of r_4 will be k as required. The last line assures that between each distinct pair of elements in r_4 there is an edge in the graph. In other words, the elements of r_4 are vertices and form a clique.

If the graph does not have a size k clique, then either of the two input relations r_1 or r_2 will be changed. By making copies of these relations before the above transformation and comparing them to the values of r_1 and r_2 after the transformation we can test whether the graph has a size k clique.

Note that we need to test not only that the graph has a clique of size k but also that it is maximal. Clearly, if k is maximal, then the graph has no clique of size $k+1$. To test that, we can reuse the above query, after an appropriate renaming of the relations. We also have to use here the input relation r_3 of size $k+1$.

$$\forall_{x_1} \exists_{x_2} : R_3 x_1 \rightarrow R_6 x_1 x_2,$$

$$\forall_{x_1} \exists_{x_2} : R_7 x_1 \rightarrow R_6 x_2 x_1,$$

$$\forall_{x_1 x_2 x_3} : R_6 x_2 x_1 \wedge R_6 x_3 x_1 \rightarrow x_2 = x_3,$$

$$\forall_{x_1 x_2 x_3} : R_6 x_1 x_2 \wedge R_6 x_1 x_3 \rightarrow x_2 = x_3,$$

$$\forall_{x_1 x_2} : R_7 x_1 \wedge R_7 x_2 \wedge x_1 \neq x_2 \rightarrow R_1 x_1 x_2.$$

The above transformation will either not change r_1 and r_3 and find a clique of size $k+1$ and place it in r_7 , or change r_1 and r_3 when there is no clique of that large size. By using again copies of r_1 and r_3 , we can tell which of the two cases occurred and construct a query that answers either true or false as required.

4. COMPUTATIONAL COMPLEXITY

In this section we will examine the computational complexity of transformation expressions. We will consider both

data and expression complexities in separate subsections. In a third subsection we also consider the special case of transformation expressions built from quantifier free formulas.

The main complexity results of this section are summarized in the following table:

Transformation class	Data complexity	Expression complexity
(τ, π)	$\in \text{co-NP}$	$\in \text{co-NEXPTIME}$
Θ	$\in \text{PSPACE}$	$\in \text{EXPSPACE}$

In this table (τ, π) denotes the class of all single transformations other than \sqcup or \sqcap , and Θ denotes the class of all transformations. For the second case we also have some lower bounds. Namely, we can prove that the data complexity of Θ is $\notin \text{NP} \cup \text{co-NP}$ and its expression complexity is $\notin \text{NEXPTIME} \cup \text{co-NEXPTIME}$, assuming the standard hypothesis in complexity theory that NP and NEXPTIME are not closed under complement [GJ79]. We also show complexity results for quantifier-free transformation expressions, which we refer to as Θ_0 .

4.1. Data Complexity

By the *data complexity* of Θ with respect to an expression θ we mean the complexity of deciding membership in the set

$$\mathcal{C}_\theta = \{ \langle db, kb \rangle \in \mathcal{DB} \times \mathcal{KB} : db \in \theta(kb) \}.$$

For the case of only one update operation the upper bound for data complexity is:

THEOREM 4.1. *For any $\theta \in (\tau, \pi)$, \mathcal{C}_θ is in co-NP .*

Proof. The case where θ is of the form π_{i_1, \dots, i_k} is obvious.

In the other case θ is of the form τ_ϕ , for some $\phi \in \Phi$. Consider the complement of \mathcal{C}_{τ_ϕ} , that is, deciding whether $db \notin \tau_\phi(kb)$. From the definition of the τ operator, it follows that there are two ways that this can be the case. Either db is not a model of ϕ , or for each $db_1 \in kb$ there is a db_2 that is a model of ϕ , and such that $db_2 <_{db_1} db$.

We guess which of these two cases holds. For the first case the verification can be done in PTIME , since deciding whether a database is a model of a given first-order formula can be done in time polynomial in the size of the database. This is because for the domain of variables B we have to take the constants that appear in either the database or the formula. Hence if we follow equations (4–8) that define models of first-order formulas, at each existential quantifier we have to test at most cardinality of B number of cases, which is linear in the size of the database. This yields a PTIME procedure for any fixed first-order formula.

For the second case, for each db_1 in kb we guess a db_2 and again we verify both of the facts that db_2 is a model of ϕ and

that $db_2 <_{db_1} db$. In other words, the symmetric difference between db_2 and db_1 must be less than the symmetric difference between db_1 and db . Since the symmetric difference between db_1 and db is at most the union of the two databases, the size of each db_2 guessed should not be greater than the input size. Hence whether db_2 is a model of ϕ can be also decided within PTIME . Finally, checking the condition $db_2 <_{db_1} db$ can obviously also be carried out in PTIME for each db_2 guessed. Since we need to guess only as many db_2 's as many databases the kb contains, we could decide in NP whether $db \notin \tau_\phi(kb)$. ■

For unrestricted composite expressions we have the following lower bound characterization.

THEOREM 4.2. *There is a θ in $(\tau, \pi)^*$, such that \mathcal{C}_θ is not in $\text{NP} \cup \text{co-NP}$, unless $\text{NP} = \text{co-NP}$.*

Proof. We will show a particular yes or no reduction from the 3CNF formula satisfiability problem. Let the given 3CNF formula ϕ be $c_1 \wedge \dots \wedge c_n$, where each c_i is of the form $l_1 \vee l_2 \vee l_3$, with each l_i being a literal. We will show that there is an expression of the form $\pi(\tau_\psi(\))$ that gives a yes or no query.

In the reduction we will use relations r_1 (representing the clauses), r_2 (representing a consistent and complete truth assignment), and r_3 (representing the clauses not satisfied by the particular assignment).

Let kb be $\{ \langle r_i \rangle \}$, where r_1 has a tuple t_i for each clause c_i of ψ . For instance, if clause c_i is $x_1 \vee \neg x_5 \vee x_8$, then t_i is $\langle i, 1, 1, 5, 0, 8, 1 \rangle$. Note that the third, fifth, and the eight elements of the tuple t_i denote by value 1 or 0 whether the literal immediately preceding them occurs positively or negatively.

Consider now the following formulas:

$$\begin{aligned} \forall_{x_1 x_2 x_3 x_4 x_5 x_6 x_7} : & R_1 x_1 x_2 x_3 x_4 x_5 x_6 x_7 \\ & \rightarrow ((R_2 x_2 0 \vee R_2 x_2 1) \\ & \wedge (R_2 x_4 0 \vee R_2 x_4 1) \\ & \wedge (R_2 x_6 0 \vee R_2 x_6 1)) \\ \forall_{x_1 x_2 x_3 x_4 x_5 x_6 x_7 x_8 x_9 x_{10}} : & (R_1 x_1 x_2 x_3 x_4 x_5 x_6 x_7 \\ & \wedge R_2 x_2 x_8 \wedge R_2 x_4 x_9 \\ & \wedge R x_6 x_{10} \wedge x_3 \neq x_8 \\ & \wedge x_5 \neq x_9 \wedge x_7 \neq x_{10}) \\ & \rightarrow R_3. \end{aligned}$$

The sentence ψ is the conjunction of the above two sentences.

Now it can be seen that if ϕ is satisfiable, then

$$\pi_3(\tau_\psi(kb)) = \{\langle \emptyset \rangle, \langle \langle \rangle \rangle\}^2$$

If ϕ is not satisfiable, then

$$\pi_3(\tau_\psi(kb)) = \{\langle \langle \rangle \rangle\}.$$

Suppose that $\mathcal{C}_{\pi_3 \tau_\psi}$ is in co-NP . Then it would be possible to solve the 3CNF satisfiability problem in co-NP . That is, we could verify in NP for each kb if there is no solution, by testing whether $\langle \emptyset \rangle \notin \pi_3(\tau_\psi(kb))$. Conversely, suppose that $\mathcal{C}_{\pi_3 \tau_\psi}$ is in NP . Then again the 3CNF problem could be solved in co-NP . This time, we would test whether $\langle \emptyset \rangle \in \pi_3(\tau_\psi(kb))$.

We know that 3CNF satisfiability problem is an NP -complete problem. Now the existence of an NP -complete problem that is in co-NP entails $\text{NP} = \text{co-NP}$. ■

For the upper bound of \mathcal{C}_θ we have:

LEMMA 4.1. *For any θ without \sqcup and \sqcap operators, the set \mathcal{C}_θ is in PSPACE .*

Proof. *W.l.o.g.* we assume that θ is of the form $\tau_{\phi_n}(\dots(\tau_{\phi_1}(\dots)))$. Let kb_0 be the input knowledgebase, and let kb_i be the knowledgebase after operation τ_{ϕ_i} is performed. In particular let kb_n be the output of the whole query, i.e., let $kb_n = \theta(kb_0)$.

Suppose that for some database db_n we know that $db_n \in \theta(kb_0)$ and we need to verify that this condition holds. We can do that by finding a db_i in each knowledgebase kb_i such that $db_i \in \tau_{\phi_i}(db_{i-1})$. In other words we must nondeterministically guess a chain of databases from an initial $db_0 \in kb_0$ to db_n and verify that in that chain each successive database db_i is a closest model of ϕ_i with respect to the previous database db_{i-1} .

To verify that a $db_i \in \tau_{\phi_i}(db_{i-1})$ we do the following. First we find the domain B that contains all the constants in either db_{i-1} or ϕ_i . Then we list all possible tuples that can be constructed from B and the relations in θ . The number of these tuples is polynomial in the size of B and db_{i-1} . Note that db_i must be a subset of these tuples, hence its size is polynomial in the size of db_{i-1} and by induction it is also polynomial in the size of db_0 and kb_0 . We have to check against each database db (that is a subset of the listed tuples) that $db_i \leq_{db_{i-1}} db$. To do that we add a one-bit tag initialized to zero to each tuple. A tag value of zero indicates that the tuple is not part of the database, while a value of one indicates that it is. We also fix some arbitrary ordering of the tags. Taking in that fixed order the tags form a counter. For each database that we get we check in polynomial

time (and space) whether it satisfies ϕ_i . If it does we have to verify that the symmetric difference of db and db_{i-1} is not less than the symmetric difference of db_i and db_{i-1} . Clearly that also can be done in PSPACE .

The above gives a NPSPACE procedure for testing whether $db_n \in \theta(kb_0)$. By Savitch's theorem, we have that $\text{NPSPACE}(n) \subseteq \text{PSPACE}(n^2)$. Hence we can also do the test in deterministic PSPACE . ■

THEOREM 4.3. *For any $\theta \in \Theta$, the set \mathcal{C}_θ is in PSPACE .*

Proof. Note that the relation symbols in θ come from a fixed set, say $\{R_1, R_2, \dots, R_n\}$, and that θ and the initial knowledgebase kb_0 have a finite set, say B , of domain elements in them. Let $\alpha(i)$ be the arity of relation R_i , and let a be the maximum arity. Suppose we want to decide whether db_n is in the knowledgebase $\theta(kb_0)$.

When each operation in θ is applied, the size of each database in the current knowledgebase can never be more than $\mathcal{O}(B^{n \cdot a})$. This is because there can be at most $B^{\alpha(i)}$ tuples over a domain B in a relation over R_i , and we have n relations. Note that $\mathcal{O}(B^{n \cdot a})$ is only a polynomial in the size of the input database and knowledgebase. Therefore, it is possible to use the technique described in Lemma 4.1 to cycle through all possible databases in PSPACE .

We claim that we can test whether db_n is in $\theta(kb_0)$ within PSPACE for any θ . To prove that we use induction. For the base case we may take any formula for θ that has in it only π and τ operations. Then by Lemma 4.1 it is possible to verify if db_n is in $\theta(kb_0)$. To check that db_n is not in $\theta(kb_0)$, we use the fact that PSPACE is closed under complement.

Now suppose that θ is of the form $\sqcap \theta'$ where θ' has in it only π and τ operations. Then we create each possible tuples using B and the relation symbols in θ . With each of these tuples, we use the technique of Lemma 4.1 again to cycle through all possible databases. As we cycle through the databases, we test using induction, whether it is in $\theta'(kb_0)$. If yes, then we read out each tuple of the database and as we read each tuple from it, we increment the counter of the corresponding tuples that we created. As we do this we also count the number of databases that are found to be in $\theta'(kb_0)$. Finally, to obtain the output, we simply delete all the counters and tuples we created except those tuples whose counter value at the end of the cycling is the same as the number of databases we found to be in $\theta'(kb_0)$. Clearly this procedure can be done in PSPACE in the size of the domain and the initial input.

It is easy to see that we can evaluate each \sqcup -operation similarly to the above and that we can continue to evaluate each successive transformation operation by cycling through again the set of possible databases and calling recursively the evaluation routine for an expression with one less operations in it. Hence we can decide in PSPACE whether $db_n \in \theta(kb_0)$ for any db_n and kb_0 . ■

² Or $\{\langle \emptyset \rangle\}$, if ϕ was a tautology.

4.2. Expression Complexity

By the *expression complexity* of Θ with respect to a pair $\langle db, kb \rangle \in \mathcal{DB} \times \mathcal{KB}$ we mean the complexity of deciding membership in the set

$$\mathcal{C}_{\langle db, kb \rangle} = \{\theta \in \Theta : db \in \theta(kb)\}.$$

THEOREM 4.4. *For any $\phi \in \Phi$ and any fixed $\langle db, kb \rangle \in \mathcal{DB} \times \mathcal{KB}$, we can test in co-NEXPTIME whether $db \in \tau_\phi(kb)$.*

Proof. We follow the same procedure as in Theorem 4.1 to test whether $db \in \tau_\phi(kb)$. Here the size of ϕ is variable. The formula can have at most $|\phi|$ existential quantifiers, where $|\phi|$ denotes the length of the formula ϕ . Hence the verification procedure may need to branch $|\phi|$ times in B ways, where B is the domain. (Note that B could vary with the size of ϕ .) Therefore $O(B^{|\phi|})$ is the worst-case time complexity, which is exponential in the size of ϕ . ■

THEOREM 4.5. *There is a $\mathcal{C}_{\langle db, kb \rangle}$ such that deciding for arbitrary $\theta \in \Theta$ whether $db \in \theta(kb)$ is not in $\text{NEXPTIME} \cup \text{co-NEXPTIME}$, unless NEXPTIME is closed under complement.*

Proof. In this proof we will simulate a nondeterministic exponential time bounded Turing machine. Let the nondeterministic exponential time Turing machine be $\mathcal{T} = \langle K, \sigma, \delta, s_0 \rangle$, where K is the set of states of the machine, σ is the alphabet, δ is the transition function, and s_0 is the initial state. Let the input tape have size n , and the computation be bounded by 2^n steps. To simplify some of the notation, throughout this proof an overline (as in \bar{x} for example) will denote binary vectors of length n .

First we use a $n+1$ -ary relation called T to describe the initial content of the tape. We create n facts $T\bar{i}, c_{\bar{i}}$, one for each $i \leq n$, where i is given in binary notation as \bar{i} . If $i > n$, then content of the i th tape cell will be a special tape symbol $\#$ denoting that it is blank. We write a sentence $\forall \bar{i} (\bar{i} \neq \bar{0} \wedge \bar{i} \neq \bar{1} \wedge \dots \wedge \bar{i} \neq \bar{n}) \rightarrow T\bar{i}, \#$, where $\bar{0}, \bar{1}, \dots, \bar{n}$ are binary expressions of the numbers from 0 to n . Let ϕ_1 be the conjunction of all the n facts and the sentence. The size of ϕ_1 is $O(n^2)$.

Second we use a 5-ary relation called D to describe the transition function δ of \mathcal{T} . We create for each possible machine input state s_{in} , input tape symbol c_{in} , output state s_{out} , tape symbol w , and movement indicator m (being n , l , or r) a fact that $Ds_{in}, c_{in}, s_{out}, w, m$ if according to δ when the machine is in state s_{in} and pointing to c_{in} , then either (1)

the machine may go to state s_{out} and point to symbol w after writing it on the tape and the move m is n , that is, no move, or (2) the machine may move one tape cell to the left and m is l , or right and m is r . (Note that if m is l or r , then w can be any tape symbol; we will not use its value anywhere later in the reduction.) Let ϕ_2 be the conjunction of all the facts described above. The size of ϕ_2 is $O(k^2 l^2)$ where k is the number of machine states and l is the number of different tape symbols.

Third we use a $2n+1$ -ary relation called C to describe the configuration of the machine. The relation $C\bar{i}, \bar{i}, s$ describes that at time step \bar{i} the machine is in state s and is pointing to tape position \bar{i} . We can assume that the Turing machine is pointing at time zero to the first tape cell. Therefore we create a fact $C0, \dots, 0, \bar{1}, s_0$. Let ϕ_3 denote this single fact. The size of ϕ_3 is $O(n)$.

Fourth we use the $2n+1$ -ary relation R to denote the sequence of nondeterministic transitions of the machine. We will express the sequence of transitions of the machine by relation $Ra_1, \dots, a_n, a_{n+1}, \dots, a_{2n}, c$ in such a way that the relation records the fact that at time t , encoded by the binary sequence a_1, \dots, a_n , the j th tape cell, where j is encoded by the binary sequence a_{n+1}, \dots, a_{2n} , contains the tape symbol c . To initialize R we write a sentence: $\forall_{x_1, \dots, x_n, y} R0, \dots, 0, x_1, \dots, x_n, y \leftrightarrow Tx_1, \dots, x_n, y$. Let ϕ_4 denote this sentence. The size of ϕ_4 is $O(n)$. (Here ϕ_4 is only for the initialization, but the expression of R will continue in ϕ_6 below.)

Fifth we use the $2n$ -ary relation S to describe the successor function limited to binary numbers of size n bits. That is, we want $S\bar{i}, \bar{o}$ to be true if and only if the binary number \bar{o} is the successor of \bar{i} , in shorthand $\bar{i} + 1 = \bar{o}$. The successor function can be expressed by a sentence of size $O(n)$ as described in [FR79]. Similarly, we use the $2n+1$ -ary relation M to describe the next tape position after the machine moves one tape cell in direction m . That is we want $M\bar{i}, \bar{i}, \text{n}$ to be true for each $0 \leq \bar{i} \leq 2^n$, and we want $M\bar{i}, \bar{o}, \text{r}$ to be true for each $0 \leq \bar{i} \leq 2^n$ and \bar{o} successor of \bar{i} , and we want $M(\bar{i}, \bar{o}, \text{l})$ to be true for each $0 \leq \bar{i} \leq 2^n$ and \bar{i} successor of \bar{o} . This can be expressed using the successor function by a sentence. Let the conjunction of the two sentence be ϕ_5 . The size of ϕ_5 is $O(n)$.

Sixth we write a sentence ϕ_6 that expresses the requirements for a valid nondeterministic computation of the machine:

$$\begin{aligned} \forall \bar{i}, \bar{i}, \bar{p}, s_{in}, s_{out}, c_{\bar{i}}, w, m : & C\bar{i} + 1, \bar{i}, s_{out} \wedge R\bar{i} + 1, \bar{i}, w \leftrightarrow m = \text{n} \wedge C\bar{i}, \bar{i}, s_{in} \wedge R\bar{i}, \bar{i}, c_{\bar{i}} \wedge Ds_{in}, c_{\bar{i}}, s_{out}, w, m \\ & \wedge \\ & C\bar{i} + 1, \bar{o}, s_{out} \leftrightarrow M\bar{i}, \bar{o}, m \wedge m \neq \text{n} \wedge C\bar{i}, \bar{i}, s_{in} \wedge R\bar{i}, \bar{i}, c_{\bar{i}} \wedge Ds_{in}, c_{\bar{i}}, s_{out}, w, m \\ & \wedge \\ & R\bar{i} + 1, \bar{p}, c_{\bar{p}} \leftrightarrow R\bar{i}, \bar{p}, c_{\bar{p}} \wedge C\bar{i}, \bar{i}, s_{in} \wedge (\bar{i} \neq \bar{p} \vee Ds_{in}, c_{\bar{i}}, s_{out}, w, \text{n}). \end{aligned}$$

This sentence says that if in time \bar{t} the machine \mathcal{T} is pointing to the \bar{t} th position and is in state s_{in} , and the content of the \bar{t} th cell is $c_{\bar{t}}$, and the transition specifies either a write or a move, then the configuration and the tape contents in the next time step will be as expected. The third part of the sentence says that the tape symbol never changes in any position (even at the current position) unless it is explicitly overwritten by the machine. The size of ϕ_6 is $O(n)$.

Seventh we write a sentence ϕ_7 that asserts that at time 2^n the machine is in the halting state h . The sentence will be $\exists \bar{p} C 1, \dots, 1, \bar{p}, h$. Thus all valid relations for R are restricted to those that lead to an accepting configuration. The size of ϕ_7 is $O(n)$.

Let θ_1 be the transformation $\tau_{\phi_1 \wedge \phi_2 \wedge \phi_3 \wedge \phi_4 \wedge \phi_5}$ and let θ_2 be the transformation $\tau_{\phi_6 \wedge \phi_7}$. Applying θ_1 to an empty initial knowledgebase will create the relations T, D, S, M and initialize C and R as required.

Let θ_3 be the transformation that copies the four relations T, D, S, M into a set of four new relations that do not occur within either θ_1 or θ_2 . We can express θ_3 by a sentence of length $O(n)$. Apply θ_3 after θ_1 .

By the minimization requirement and definition (9), whenever it is possible applying θ_2 after θ_3 will result in a valid R and T, D, S, M and the initialization of R and C unchanged, otherwise either one or more of these four relations will change or the initial value of R or C will change.

Similarly to Example 5, after performing θ_2 we can use another transformation θ_4 that makes a binary output relation r_0 the empty relation if and only if there were no changes to T, D, S, M and the initialization of R and C , otherwise r_0 will be the relation with the empty tuple. We can write θ_4 such that it projects out any other relations beside r_0 , so that only r_0 remains. The size of θ_4 will be $O(n)$.

Let θ_5 denote the complete transformation expression, that is, $\theta_4(\theta_2(\theta_3(\theta_1(\))))$. The size of θ_5 is $O(n^2 + k^2 l^2)$.

Suppose then that the language $\mathcal{C}_{\langle db, kb \rangle}$ is in NEXPTIME for any kb and every database db . We fix kb_0 to be the empty knowledgebase. Let db_0 be the database with the only relation r_0 and r_0 being the empty relation. Then using the transformation θ_5 we could decide in NEXPTIME in the size of θ_5 , whether $db_0 \in \theta_5(kb_0)$. Now let db_1 be the database that contains the only relation relation r_0 , and r_0 contains the empty tuple. We could now decide in NEXPTIME whether $db_1 \in \theta_5(kb)$.

Note that we can describe by any fixed NEXPTIME bounded Turing machine and any variable input string of length n by some θ_5 of length polynomial in n . Therefore, if the language $\mathcal{C}_{\langle db, kb \rangle}$ is in NEXPTIME for every db and every kb , then the question of whether the input tape is accepted by an NEXPTIME bounded Turing machine is in co-NEXPTIME . This in turn implies that NEXPTIME is closed under complement. Hence unless NEXPTIME is indeed closed by complement, the language $\mathcal{C}_{\langle db, kb \rangle}$ is not in NEXPTIME. We can argue similarly that the language is

also not in co-NEXPTIME using the fact that we have an if and only if transformation. ■

For the upperbound we have in general that:

THEOREM 4.6. *For any $\langle db, kb \rangle \in \mathcal{DB} \times \mathcal{KB}$, the set $\mathcal{C}_{\langle db, kb \rangle}$ is in EXPSPACE.*

Proof. The maximum size of any database in the current knowledgebase during testing will be bounded as in Theorem 4.3. In the present case the domain B is fixed, but the maximum arity a and the number of relations n in the databases are variable. Hence the expression complexity will be the EXPSPACE, and we can show that by using the same algorithm as in Theorem 4.3 together with the fact that EXPSPACE is closed under complement. ■

4.3. Some Special Cases

In this section we consider two special cases of the transformation language: (1) quantifier-free transformations and (2) Datalog-restricted transformations. By quantifier-free transformations we mean expressions in which all sentences used to update the knowledgebase are boolean combinations of ground atomic formulas, i.e., formulas in which each argument of each relation is a constant. By Datalog-restricted transformations we mean transformation expressions in which all sentences are conjunctions of function-free Horn clauses.

THEOREM 4.7. *If θ is quantifier free, then $\mathcal{C}_{\tau_\theta}$ is in PTIME.*

Proof. Since each sentence of θ is quantifier free, we need to make a fixed number of transformations of the form \sqcup, \sqcap , or τ_ϕ where ϕ is a quantifier free sentence. Transformations \sqcup and \sqcap can clearly be done in linear time in the size of the knowledgebase using the same procedure as in Theorem 4.3 For performing τ_ϕ we have to test all truth assignments to ϕ that can be minimal models. Each of these models will be a database which is the union of the ground facts that occur only in the input database and some ground atoms in ϕ assigned to be either false (i.e., not occur in the corresponding relation) or true (i.e., occur in the corresponding relation). Since the number of grounds atoms that need to be considered is fixed and bounded by the size of ϕ , all possible minimal databases can be found and tested whether they are models of ϕ in PTIME. ■

For the data complexity of transformations with the second restriction we have:

THEOREM 4.8. *If θ is a Datalog-restricted transformation, then $\mathcal{C}_{\tau_\theta}$ is in PTIME.*

Proof. Here we need to make a fixed number of transformations of the form \sqcup, \sqcap , or τ_ϕ where ϕ is a Datalog program. Again, transformations \sqcup and \sqcap can clearly be done in linear time in the size of the knowledgebase. For

showing that performing τ_ϕ can be done in PTIME it is enough to recall that Datalog programs have a unique least model that can be computed using naive evaluation in PTIME. ■

For the expression complexity, when θ is quantifier free the transformation language has the following bound:

THEOREM 4.9. $\mathcal{C}_{\langle db, kb \rangle}$ is not in $\text{NP} \cup \text{co-NP}$, unless NP is closed under complement, even if $\theta \in \Theta_0$ and is quantifier free.

Proof. This follows by a reduction from the problem of satisfiability of propositional formulas [GJ79]. Take the case when db and kb both contain a single zero-ary relation r_0 that is assigned to be true (i.e., contains the empty tuple). Any propositional formula can be expressed by a sentence ϕ' using zero-ary relation symbols different from R_0 . Then let ϕ be the sentence $\phi' \rightarrow R_0$.

Since r_0 is an input relation, r_0 will not be changed unless necessary, which occurs if and only if ϕ' has no model. Hence the formula ϕ' is satisfiable if and only if after the projection π_0 , the relation r_0 still contains the empty tuple, i.e., $db \in \pi_0 \tau_\phi(kb)$ as required. Similarly to Theorem 4.5 this leads to the conclusion that the problem is not in $\text{NP} \cup \text{co-NP}$ unless NP is closed under complement. ■

Remark. Grahne and Mendelzon [GM95] have studied the complexity of evaluating *subjunctive queries* in a propositional language, and found the data complexity of such a language to be in PTIME and the expression complexity to be in PSPACE. The quantifier-free case of our language does not have subjunctive implication operators in it, otherwise it would be a proper superset of the language in [GM95]. For other complexity theoretic issues in belief revision and updates we refer the reader to [EG982, EG93, GM95].

5. EXPRESSIVE POWER

Let YF, SF, and SO be the class of all transformations from databases to databases expressible, respectively, by fixpoint queries, existential second-order queries, and second-order queries, as defined in [CH82, Var82]. It is well-known that YF is properly included in SF and that SF is also included in SO [Var82].

In order to relate our language to the above classes of transformations, we shall restrict ourselves to the case where all input knowledgebases are singletons, i.e. databases, and we will restrict the language so that all output knowledgebases are also singletons. From this restriction follows that the expressive power results that are lower-bounds in this section will carry over to the general case, but the significance of the upper bounds is primarily in the comparison with other languages. Let ST be the class of all transformations from singleton knowledgebases to

singleton knowledgebases, expressible by a transformation in Θ of the form $(\pi b \tau)^*$, where each b is one of \sqcap or \sqcup .

As we noted in Section 2, the transformations described by expressions in this class fall within the class of *deterministic updates* defined by Abiteboul and Vianu. It follows immediately that every query in ST is expressible in their languages detTL and detDL , which are shown in [AV88] to express all deterministic updates. It follows from Theorem 5.2 below that this inclusion is proper, since ST does not go beyond the second order queries SO.

However, ST does include all the existential second-order queries: let ST^i denote the subclass of ST expressions that use at most i compositions of subexpressions of the form $\pi b \tau$. Then all existential second-order queries can be expressed within ST^1 .

THEOREM 5.1. $\text{SF} \subseteq \text{ST}^1$.

Proof. Without loss of generality let $\bar{x}.\exists R_{n+1}\phi(\bar{x})$ be any existential second order query. Let a be the arity of R_{n+1} and let the set of relation symbols in ϕ be $\{R_1, \dots, R_n, R_{n+1}\}$. (Note that a is also the size of \bar{x} . The size of \bar{x} could be smaller if we added extra projection operations.) By the standard definition [Var82] the image of this query under a database $\langle D, r_1, \dots, r_n \rangle$ is $\{\bar{d} \in D^{|\bar{x}|} : \text{there is a relation } r_{n+1} \subseteq D^a \text{ such that } \phi(\bar{d}) \text{ is true in } (D, r_1, \dots, r_{n+1})\}$.

Instead of a fixed domain as in [Var82], we take D to be the set of constants in ϕ and in the input relations r_1, \dots, r_n . Therefore the possible values of r_{n+1} are finite and can be listed. There would be exactly $2^{|D|^a}$ number of possibilities for r_{n+1} . Therefore we can construct a knowledgebase kb that has in it exactly that many databases with each database containing r_1, \dots, r_n and one of the possible r_{n+1} . Then the query can be expressed as a transformation as follows. We create a new relation r_{n+2} to present the output of the query. Then we write

$$\pi_{n+2} \sqcup \tau_{(\forall \bar{x} \phi(\bar{x}) \rightarrow R_{n+2}(\bar{x}))}(kb).$$

This transformation always takes in set of databases, with each database having schema $\{R_1, \dots, R_{n+1}\}$. The input database is never changed because the implication $\forall \bar{x} \phi(\bar{x}) \rightarrow R_{n+2}(\bar{x})$ can always be satisfied by adding the required tuples for \bar{x} to r_{n+2} . By the minimality requirement, r_{n+2} will always have only those tuples in it which satisfy $\phi(\bar{x})$. If no tuples satisfy $\phi(\bar{x})$, then r_{n+2} will be an empty relation. Also by the minimality requirement, none of the other relations are changed. The projection π_{n+2} simply returns the desired output, that is, the set of tuples that satisfy the existential second order formula, for some value of r_{n+1} . ■

By Theorem 5.1 any SF query can be expressed by a transformation expression of the form $\pi \sqcup \tau$. An interesting

question is what can be gained in expressive power by the composition of $\pi b\tau$ transformations. The following theorem gives a partial answer to that question, namely that the composition cannot increase the expressive power beyond SO.

THEOREM 5.2. $ST \subseteq SO$.

Proof. Clearly the theorem is proved by demonstrating there is a logspace reduction from ST to an equivalent transformation in SO.

First we consider the case where θ is of the form $\pi_{i_j} \sqcup \tau_\phi$, where $j \in \{1, \dots, n\}$, $\sigma = (db) = \{R_{i_1}, \dots, R_{i_n}\}$, and $\{R'_{i_j}\} \subseteq \sigma(\phi) \subseteq \{R_{i_1}, \dots, R_{i_n}\}$. In the second-order syntax we therefore sometimes write ϕ as $\phi(R_{i_1}, \dots, R_{i_n})$.

Suppose that the arity of R'_{i_j} is k , and for each i let R'_i and S_i be rational variables of the same arity as R_i . The corresponding second-order query would then be

$$x_1 x_2 \cdots x_k \cdot \exists R'_{i_1} \cdots \exists R'_{i_n} \forall S_{i_1} \cdots \forall S_{i_n} \\ : \varphi(x_1 x_2 \cdots x_k, R_{i_1}, \dots, R_{i_n}, R'_{i_1}, \dots, R'_{i_n}),$$

where φ is the formula

$$R'_{i_j}(x_1 x_2 \cdots x_k) \wedge \phi(R'_{i_1}, \dots, R'_{i_n}) \\ \wedge \min(\phi, R_{i_1}, \dots, R_{i_n}, R'_{i_1}, \dots, R'_{i_n}).$$

Here $\min(\phi, \dots)$ is an abbreviation of the formula

$$\left(\phi(S_{i_1}, \dots, S_{i_n}) \wedge \left(\bigwedge_{j=1}^n (S_{i_j} \leq_{R_{i_j}} R'_{i_j}) \right) \right) \\ \rightarrow \left(\bigwedge_{j=1}^n (R'_{i_j} \leq_{R_{i_j}} S_{i_j}) \right),$$

where $S_{i_j} \leq_{R_{i_j}} R'_{i_j}$ abbreviates

$$\forall_{x_1 x_2 \cdots x_k} : ((S_{i_j} x_1 x_2 \cdots x_k \wedge \neg R_{i_j} x_1 x_2 \cdots x_k) \\ \vee (R_{i_j} x_1 x_2 \cdots x_k \wedge \neg S_{i_j} x_1 x_2 \cdots x_k)) \\ \rightarrow ((R'_{i_j} x_1 x_2 \cdots x_k \wedge \neg R_{i_j} x_1 x_2 \cdots x_k) \\ \vee (R_{i_j} x_1 x_2 \cdots x_k \wedge \neg R'_{i_j} x_1 x_2 \cdots x_k)),$$

and likewise for $R'_{i_j} \leq_{R_{i_j}} S_{i_j}$.

It can now be verified that for any $db \in \mathcal{DB}$, the transformation expression θ and the above second-order query return the same result when applied to $\{db\}$.

If θ is of the form $\pi_{i_j} \sqcap \tau_\phi$, then the corresponding second-order query is

$$x_1 x_2 \cdots x_k \cdot \forall R'_{i_1} \cdots \forall R'_{i_n} : (\phi(R'_{i_1}, \dots, R'_{i_n}) \wedge \min(\phi, \dots)) \\ \rightarrow R'_{i_j} x_1 x_2 \cdots x_k.$$

Note the similarity between these second-order queries and circumscription [McC80].

To proceed, if θ is of the form $\pi_{i_{n+1}} \sqcup \tau_\phi$ where $\sigma(db) = \{R_{i_1}, \dots, R_{i_n}\}$, and $\{R_{i_{n+1}}\} \subseteq \sigma(\phi) \subseteq \{R_{i_1}, \dots, R_{i_n}, R_{i_{n+1}}\}$, then we apply a slight variation of the basic reduction including the necessary modification to the formula $S_{i_j} \leq_{R_{i_j}} R'_{i_j}$ (cf. definitions (1)–(3)).

Furthermore, if the projection in θ is on several component relations, we define a vector of second-order queries.

Finally, if θ is a composition of several $\pi b\tau$ -expression, the corresponding second-order query will be obtained by composing the more elementary queries. ■

Since $SO = QPHIER$, the existence of a logspace reduction for unrestricted expressions in Θ to queries in SO would place the θ transformations within the polynomial hierarchy.

Abiteboul, Simon and Vianu [ASV90] have studied retractions of the update languages that we mentioned at the beginning of this section and characterized their expressive power in terms of complexity classes. Their approach is to transform non-deterministic languages into deterministic ones by either taking the union of all the possible output databases computed for each input database (which they call the *possibility semantics*) or taking the intersection (*certainty semantics*). Since the \sqcup operator corresponds naturally to possibility semantics and \sqcap to certainty, it seems that the languages of [ASV90] should be closely connected to various subclasses of ST transformations, but we have not yet explored this in detail.

6. CONCLUSIONS AND OPEN PROBLEM

We propose in this paper a simple and versatile language that unifies queries and updates. There are a few other proposals in that direction, but our language has to its advantage that its basic operator for update satisfies all the Katsuno–Mendelzon postulates, which capture intuitive requirements on the notion of update.

Our work leaves open the precise computational complexity and expressive power of the transformation language. Our conjecture is that if we restrict to a constant the number of nested transformations in Lemma 4.1 then we are likely to end up in the polynomial hierarchy PHIER. It would be also good to get tighter lower and upper bounds for the data complexity of transformation expressions that we know lies between the upper bound of PSPACE and the lower bound of not in $NP \cup \text{co-NP}$. To tighten this and other bounds would require a deeper understanding of the nature of the \sqcap and \sqcup operators which are unique to this paper.

Another interesting direction of research would be to investigate the relationship between hypothetical queries and the proposed transformation language. Finally, it

would be challenging to look for suitable specific application areas, and perhaps tailor the transformation language to those by adding application-specific operators.
