- Machine learning can generally be distilled to an optimization problem
- Choose a classifier (function, hypothesis) from a set of functions that minimizes an objective function
- Clearly we want part of this function to measure performance on the training set, but this is insufficient

- Types of machine learning problems
- Loss functions
- Generalization performance vs training set performance
- Overfitting
- Regularization
- Estimating generalization performance

- **Supervised Learning:** Algorithm is given labeled *training data* and is asked to infer a function (*hypothesis*) from a family of functions (e.g., set of all ANNs) that is able to predict well on new, unseen examples
  - **Classification:** Labels come from a finite, discrete set
  - **Regression:** Labels are real-valued
- **Unsupervised Learning:** Algorithm is given data without labels and is asked to model its structure
  - Clustering, density estimation
- **Reinforcement Learning:** Algorithm controls an agent that interacts with its environment and learns good actions in various situations

Algorithms

Other  
Performance  
Measures

- In any learning problem, need to be able to quantify performance of an algorithm
- In supervised learning, we often use a **loss function** (or error function)  $\mathcal{J}$  for this task
- Given instance  $x$  with true label  $y$ , if the learner's prediction on  $x$  is  $\hat{y}$ , then

$$\mathcal{J}(y, \hat{y})$$

is the loss on that instance

# Measuring Performance

## Examples of Loss Functions

Regularization

Estimating  
Generalization  
Performance

Comparing  
Learning  
Algorithms

Other

- **0-1 Loss:**  $\mathcal{J}(y, \hat{y}) = 1$  if  $y \neq \hat{y}$ , 0 otherwise
- **Square Loss:**  $\mathcal{J}(y, \hat{y}) = (y - \hat{y})^2$
- **Cross-Entropy:**  $\mathcal{J}(y, \hat{y}) = -y \ln \hat{y} - (1 - y) \ln (1 - \hat{y})$   
( $y$  and  $\hat{y}$  are considered probabilities of a '1' label;  
generalizes to multi-class.)
- **Hinge Loss:**  $\mathcal{J}(y, \hat{y}) = \max(0, 1 - y \hat{y})$   
(used sometimes for large margin classifiers like SVMs)

All non-negative

- Given a loss function  $\mathcal{J}$  and a training set  $\mathcal{X}$ , the total loss of the classifier  $h$  on  $\mathcal{X}$  is

$$\text{error}_{\mathcal{X}}(h) = \sum_{\mathbf{x} \in \mathcal{X}} \mathcal{J}(y_{\mathbf{x}}, \hat{y}_{\mathbf{x}}) ,$$

where  $y_{\mathbf{x}}$  is  $\mathbf{x}$ 's label and  $\hat{y}_{\mathbf{x}}$  is  $h$ 's prediction

- More importantly, the learner needs to **generalize** well: Given a new example drawn iid according to unknown probability distribution  $\mathcal{D}$ , we want to minimize  $h$ 's **expected loss**:

$$error_{\mathcal{D}}(h) = \mathbb{E}_{\mathbf{x} \sim \mathcal{D}} [\mathcal{J}(y_{\mathbf{x}}, \hat{y}_{\mathbf{x}})]$$

- Is minimizing training loss the same as minimizing expected loss?

- Sufficiently sophisticated learners (decision trees, multi-layer ANNs) can often achieve arbitrarily small (or zero) loss on a training set
- A hypothesis (e.g., ANN with specific parameters)  $h$  *overfits* the training data  $\mathcal{X}$  if there is an alternative hypothesis  $h'$  such that

$$\text{error}_{\mathcal{X}}(h) < \text{error}_{\mathcal{X}}(h')$$

and

$$\text{error}_{\mathcal{D}}(h) > \text{error}_{\mathcal{D}}(h')$$

Estimating  
Generalization  
Performance

- Generally, if the set of functions  $\mathcal{H}$  the learner has to choose from is complex relative to what is required for correctly predicting the labels of  $\mathcal{X}$ , there's a larger chance of overfitting due to the large number of “wrong” choices in  $\mathcal{H}$ 
  - Could be due to an overly sophisticated set of functions
    - E.g., can fit any set of  $n$  real-valued points with an  $(n - 1)$ -degree polynomial, but perhaps only degree 2 is needed
    - E.g., using an ANN with 5 hidden layers to solve the logical AND problem
  - Could be due to training an ANN too long
    - Over-training an ANN often leads to weights deviating far from zero
    - Makes the function more non-linear, and more complex
- Often, a larger data set mitigates the problem

Data Augmentation  
Multitask Learning  
Dropout

Others

Estimating  
Generalization  
Performance

- Danger of stopping too soon
  - “Patience” parameter determines how long to wait
- Can re-start and track best one on separate validation set

- Still want to minimize training loss, but balance it against a complexity penalty on the parameters used:

$$\tilde{\mathcal{J}}(\boldsymbol{\theta}; \mathcal{X}, \mathbf{y}) = \mathcal{J}(\boldsymbol{\theta}; \mathcal{X}, \mathbf{y}) + \alpha \Omega(\boldsymbol{\theta})$$

- $\alpha \in [0, \infty)$  weights loss  $\mathcal{J}$  against penalty  $\Omega$

- $\Omega(\boldsymbol{\theta}) = (1/2)\|\boldsymbol{\theta}\|_2^2$ , i.e., sum of squares of network's weights
- Since  $\boldsymbol{\theta} = \mathbf{w}$ , this becomes

$$\tilde{\mathcal{J}}(\mathbf{w}; \mathcal{X}, \mathbf{y}) = (\alpha/2)\mathbf{w}^\top \mathbf{w} + \mathcal{J}(\mathbf{w}; \mathcal{X}, \mathbf{y})$$

- As weights deviate from zero, activation functions become more nonlinear, which is higher risk of overfitting

# Regularization

Parameter Norm Penalties:  $L^2$  Norm

- $w^*$  is optimal for  $\mathcal{J}$ ,  $\mathbf{0}$  optimal for regularizer
- $\mathcal{J}$  less sensitive to  $w_1$ , so  $\tilde{w}$  (optimal for  $\tilde{\mathcal{J}}$ ) closer to  $w_2$  axis than  $w_1$

CSCE 970  
Lecture 3:

Early Stopping

Parameter Norm  
Penalties

Data Augmentation  
Multitask Learning

Dropout

Others

Estimating  
Generalization  
Performance

- $\Omega(\boldsymbol{\theta}) = \|\boldsymbol{\theta}\|_1$ , i.e., sum of absolute values of network's weights

$$\tilde{\mathcal{J}}(\mathbf{w}; \mathcal{X}, \mathbf{y}) = \alpha \|\mathbf{w}\|_1 + \mathcal{J}(\mathbf{w}; \mathcal{X}, \mathbf{y})$$

- As with  $L^2$  regularization, penalizes large weights
- Unlike  $L^2$  regularization, can drive some weights to zero
  - **Sparse** solution
  - Sometimes used in **feature selection** (e.g., LASSO algorithm)

- If  $\mathcal{H}$  powerful and  $\mathcal{X}$  small, then learner can choose some  $h \in \mathcal{H}$  that fits idiosyncrasies or noise in data
- Deep ANNs would like to have at least thousands or tens of thousands of data points
- In classification of high-dimensional data (e.g., image classification), expect the classifier to tolerate transformations and noise
  - ⇒ Can artificially enlarge data set by duplicating existing instances and applying transformations
    - Translating, rotating, scaling
    - Don't change the class, e.g., "b" vs "d" or "6" vs "9"
    - **Don't let duplicates lie in both training and testing sets**
  - ⇒ Can also apply noise injection to input or hidden layers

Early Stopping  
Parameter Norm  
Penalties

Data Augmentation

Multitask Learning  
Dropout  
Others

Estimating  
Generalization  
Performance

- If multiple tasks share **generic parameters**, initially process inputs via shared nodes, then do final processing via task-specific nodes
- Backpropagation works as before with multiple output nodes
- Serves as a regularizer since parameter tuning of shared nodes is based on backpropagated error from multiple tasks

# Regularization

## Dropout

- Imagine if, for a network, we could average over all networks with each subset of nodes deleted
- Analogous to **bagging**, where we average over ANNs trained on random samples of  $\mathcal{X}$
- In each training iteration, sample a random bit vector  $\mu$ , which determines which nodes are used (e.g.,  $P(\mu_i = 1) = 0.8$  for input unit, 0.5 for hidden unit)

- When training done, re-scale weights by  $P(\mu_i = 1)$

- **Parameter Tying:** If two learners are learning the same task but different scenarios (distributions, etc.), can tie their parameters together
  - If  $\mathbf{w}^{(A)}$  are weights for task  $A$  and  $\mathbf{w}^{(B)}$  are weights for task  $B$ , then can use regularization term
$$\Omega(\mathbf{w}^{(A)}, \mathbf{w}^{(B)}) = \|\mathbf{w}^{(A)} - \mathbf{w}^{(B)}\|_2^2$$
  - E.g.,  $A$  is supervised and  $B$  is unsupervised
- **Parameter Sharing:** When detecting objects in an image, the same recognizer should apply invariant to translation
  - Train a single detector (subnetwork) for an object (e.g., cat) by training full network on multiple images with translated cats, where the cat detector subnets share parameters (single copy, used multiple times)

- **Sparse Representations:** Instead of penalizing large weights, penalize large outputs of hidden nodes:

$$\tilde{\mathcal{J}}(\boldsymbol{\theta}; \mathcal{X}, \mathbf{y}) = \mathcal{J}(\boldsymbol{\theta}; \mathcal{X}, \mathbf{y}) + \alpha \Omega(\mathbf{h}) ,$$

where  $\mathbf{h}$  is the vector of hidden unit outputs

# Estimating Generalization Performance

## Setting Goals

Generalization  
Performance

Setting Goals

Confidence Intervals

Comparing  
Learning  
Algorithms

Other / 52

- Before setting up an experiment, need to understand exactly what the goal is
  - Estimate the generalization performance of a hypothesis
  - Tuning a learning algorithm's parameters
  - Comparing two learning algorithms on a specific task
  - Etc.
- Will never be able to answer the question with 100% certainty
  - Due to variances in training set selection, test set selection, etc.
  - Will choose an **estimator** for the quantity in question, determine the probability distribution of the estimator, and bound the probability that the estimator is way off
  - Estimator needs to work regardless of distribution of training/testing data

# Estimating Generalization Performance

## Setting Goals

- Need to note that, in addition to statistical variations, what we determine is limited to the application that we are studying
  - E.g., if  $ANN_1$  better than  $ANN_2$  on speech recognition, that means nothing about video analysis
- In planning experiments, need to ensure that training data not used for evaluation
  - I.e., **don't test on the training set!**
  - Will bias the performance estimator
  - If using data augmentation, **don't let duplicates lie in both training and testing sets**
  - Also holds for **validation set** used for early stopping, tuning parameters, etc.
    - Validation set serves as part of training set, but not used for model building

Let  $error_{\mathcal{D}}(h)$  be 0-1 loss of hypothesis  $h$  on instances drawn according to distribution  $\mathcal{D}$ . If

- Test set  $\mathcal{V}$  contains  $N$  examples, drawn independently of  $h$  and each other
- $N \geq 30$

Then with approximately 95% probability,  $error_{\mathcal{D}}(h)$  lies in

$$error_{\mathcal{V}}(h) \pm 1.96 \sqrt{\frac{error_{\mathcal{V}}(h)(1 - error_{\mathcal{V}}(h))}{N}}$$

E.g. hypothesis  $h$  misclassifies 12 of the 40 examples in test set  $\mathcal{V}$ :

$$error_{\mathcal{V}}(h) = \frac{12}{40} = 0.30$$

Then with approx. 95% confidence,  $error_{\mathcal{D}}(h) \in [0.158, 0.442]$

Let  $error_{\mathcal{D}}(h)$  be 0-1 loss of  $h$  on instances drawn according to distribution  $\mathcal{D}$ . If

- Test set  $\mathcal{V}$  contains  $N$  examples, drawn independently of  $h$  and each other
- $N \geq 30$

Then with approximately  $c\%$  probability,  $error_{\mathcal{D}}(h)$  lies in

$$error_{\mathcal{V}}(h) \pm z_c \sqrt{\frac{error_{\mathcal{V}}(h)(1 - error_{\mathcal{V}}(h))}{N}}$$

$N\%$ :	50%	68%	80%	90%	95%	98%	99%
$z_c$ :	0.67	1.00	1.28	1.64	1.96	2.33	2.58

Why?

# $error_{\mathcal{V}}(h)$ is a Random Variable

Setting Goals

Confidence Intervals

Comparing  
Learning  
Algorithms

Other / 52

$$P(r) = \binom{N}{r} p^r (1-p)^{N-r} = \frac{N!}{r!(N-r)!} p^r (1-p)^{N-r}$$

Probability  $P(r)$  of  $r$  heads in  $N$  coin flips, if  $p = \Pr(\text{heads})$

- Expected, or mean value of  $X$ ,  $\mathbb{E}[X]$  (= # heads on  $N$  flips = # mistakes on  $N$  test exs), is

$$\mathbb{E}[X] \equiv \sum_{i=0}^N iP(i) = Np = N \cdot \text{error}_{\mathcal{D}}(h)$$

- Variance of  $X$  is

$$\text{Var}(X) \equiv \mathbb{E}[(X - \mathbb{E}[X])^2] = Np(1-p)$$

- Standard deviation of  $X$ ,  $\sigma_X$ , is

$$\sigma_X \equiv \sqrt{\mathbb{E}[(X - \mathbb{E}[X])^2]} = \sqrt{Np(1-p)}$$

$error_{\mathcal{V}}(h) = r/N$  is binomially distributed, with

- mean  $\mu_{error_{\mathcal{V}}(h)} = error_{\mathcal{D}}(h)$  (i.e., unbiased est.)
- standard deviation  $\sigma_{error_{\mathcal{V}}(h)}$

$$\sigma_{error_{\mathcal{V}}(h)} = \sqrt{\frac{error_{\mathcal{D}}(h)(1 - error_{\mathcal{D}}(h))}{N}}$$

(increasing  $N$  decreases variance)

Want to compute confidence interval = interval centered at  $error_{\mathcal{D}}(h)$  containing  $c\%$  of the weight under the distribution

Approximate binomial by **normal** (Gaussian) dist:

- mean  $\mu_{error_{\mathcal{V}}(h)} = error_{\mathcal{D}}(h)$
- standard deviation  $\sigma_{error_{\mathcal{V}}(h)}$

$$\sigma_{error_{\mathcal{V}}(h)} \approx \sqrt{\frac{error_{\mathcal{V}}(h)(1 - error_{\mathcal{V}}(h))}{N}}$$

$$p(x) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left(-\frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2\right)$$

- The probability that  $X$  will fall into the interval  $(a, b)$  is given by  $\int_a^b p(x) dx$
- Expected, or mean value of  $X$ ,  $\mathbb{E}[X]$ , is  $\mathbb{E}[X] = \mu$
- Variance is  $Var(X) = \sigma^2$ , standard deviation is  $\sigma_X = \sigma$

80% of area (probability) lies in  $\mu \pm 1.28\sigma$

$c\%$  of area (probability) lies in  $\mu \pm z_c \sigma$

$c\%$ :	50%	68%	80%	90%	95%	98%	99%
$z_c$ :	0.67	1.00	1.28	1.64	1.96	2.33	2.58

Can also have **one-sided** bounds:

$c\%$  of area lies  $< \mu + z'_c \sigma$  or  $> \mu - z'_c \sigma$ , where

$$z'_c = z_{100-(100-c)/2}$$

$c\%$ :	50%	68%	80%	90%	95%	98%	99%
$z'_c$ :	0.0	0.47	0.84	1.28	1.64	2.05	2.33

# Confidence Intervals Revisited

If  $\mathcal{V}$  contains  $N \geq 30$  examples, indep. of  $h$  and each other

Then with approximately 95% probability,  $error_{\mathcal{V}}(h)$  lies in

$$error_{\mathcal{D}}(h) \pm 1.96 \sqrt{\frac{error_{\mathcal{D}}(h)(1 - error_{\mathcal{D}}(h))}{N}}$$

Equivalently,  $error_{\mathcal{V}}(h)$  lies in

$$error_{\mathcal{V}}(h) \pm 1.96 \sqrt{\frac{error_{\mathcal{D}}(h)(1 - error_{\mathcal{D}}(h))}{N}}$$

which is approximately

$$error_{\mathcal{V}}(h) \pm 1.96 \sqrt{\frac{error_{\mathcal{V}}(h)(1 - error_{\mathcal{V}}(h))}{N}}$$

**(One-sided bounds yield upper or lower error bounds)**

How can we justify approximation?

Consider set of iid random variables  $Y_1, \dots, Y_N$ , all from **arbitrary** probability distribution with mean  $\mu$  and finite variance  $\sigma^2$ . Define sample mean  $\bar{Y} \equiv (1/N) \sum_{i=1}^n Y_i$

$\bar{Y}$  is itself a random variable, i.e., result of an experiment (e.g.,  $error_S(h) = r/N$ )

**Central Limit Theorem:** As  $N \rightarrow \infty$ , the distribution governing  $\bar{Y}$  approaches normal distribution with mean  $\mu$  and variance  $\sigma^2/N$

Thus the distribution of  $error_S(h)$  is approximately normal for large  $N$ , and its expected value is  $error_{\mathcal{D}}(h)$

**(Rule of thumb:**  $N \geq 30$  when estimator's distribution is binomial; might need to be larger for other distributions)

- 1 Pick parameter to estimate:  $error_{\mathcal{D}}(h)$   
(0-1 loss on distribution  $\mathcal{D}$ )
- 2 Choose an estimator:  $error_{\mathcal{V}}(h)$   
(0-1 loss on independent test set  $\mathcal{V}$ )
- 3 Determine probability distribution that governs estimator:  $error_{\mathcal{V}}(h)$  governed by binomial distribution, approximated by normal when  $N \geq 30$
- 4 Find interval  $(L, U)$  such that  $c\%$  of probability mass falls in the interval
  - Could have  $L = -\infty$  or  $U = \infty$
  - Use table of  $z_c$  or  $z'_c$  values (if distribution normal)

$K$ -Fold CV

Student's  $t$   
Distribution

38 / 52

Other

- What if we want to compare two learning algorithms  $L^1$  and  $L^2$  (e.g., two ANN architectures, two regularizers, etc.) on a specific application?
- Insufficient to simply compare error rates on a single test set
- Use  **$K$ -fold cross validation** and a **paired  $t$  test**

- 1 Partition data set  $\mathcal{X}$  into  $K$  equal-sized subsets  $\mathcal{X}_1, \mathcal{X}_2, \dots, \mathcal{X}_K$ , where  $|\mathcal{X}_i| \geq 30$
- 2 For  $i$  from 1 to  $K$ , do  
(Use  $\mathcal{X}_i$  for testing, and rest for training)
  - 1  $\mathcal{V}_i = \mathcal{X}_i$
  - 2  $\mathcal{T}_i = \mathcal{X} \setminus \mathcal{X}_i$
  - 3 Train learning algorithm  $L^1$  on  $\mathcal{T}_i$  to get  $h_i^1$
  - 4 Train learning algorithm  $L^2$  on  $\mathcal{T}_i$  to get  $h_i^2$
  - 5 Let  $p_i^j$  be error of  $h_i^j$  on test set  $\mathcal{V}_i$
  - 6  $p_i = p_i^1 - p_i^2$
- 3 Error difference estimate  $p = (1/K) \sum_i^K p_i$

- Now estimate confidence that true expected error difference  $< 0$
- ⇒ Confidence that  $L^1$  is better than  $L^2$  on learning task
- Use **one-sided test**, with confidence derived from **student's  $t$  distribution** with  $K - 1$  **degrees of freedom**
  - With approximately  $c\%$  probability, true difference of expected error between  $L^1$  and  $L^2$  is at most

$$p + t_{c,K-1} s_p$$

where

$$s_p \equiv \sqrt{\frac{1}{K(K-1)} \sum_{i=1}^K (p_i - p)^2}$$

If  $p + t_{c,K-1} s_p < 0$  our assertion that  $L^1$  has less error than  $L^2$  is supported with confidence  $c$

So if  $K$ -fold CV used, compute  $p$ , look up  $t_{c,K-1}$  and check if  $p < -t_{c,K-1} s_p$

**One-sided test; says nothing about  $L^2$  over  $L^1$**

- Say you want to show that learning algorithm  $L^1$  performs better than algorithms  $L^2, L^3, L^4, L^5$
- If you use  $K$ -fold CV to show superior performance of  $L^1$  over each of  $L^2, \dots, L^5$  at 95% confidence, there's a 5% chance each one is wrong
- ⇒ There's an over 18.5% chance that at least one is wrong
- ⇒ Our overall confidence is only just over 81%
- Need to account for this, or use more appropriate test

- So far, we've looked at a single error rate to compare hypotheses/learning algorithms/etc.
- This may not tell the whole story:
  - 1000 test examples: 20 positive, 980 negative
  - $h^1$  gets 2/20 pos correct, 965/980 neg correct, for accuracy of  $(2 + 965)/(20 + 980) = 0.967$
  - Pretty impressive, except that always predicting negative yields accuracy = 0.980
  - Would we rather have  $h^2$ , which gets 19/20 pos correct and 930/980 neg, for accuracy = 0.949?
  - Depends on how important the positives are, i.e., frequency in practice and/or cost (e.g., cancer diagnosis)

Break down error into type: true positive, etc.

True Class	Predicted Class		
	Positive	Negative	Total
Positive	$tp$ : true positive	$fn$ : false negative	$p$
Negative	$fp$ : false positive	$tn$ : true negative	$n$
Total	$p'$	$n'$	$N$

- Generalizes to multiple classes
- Allows one to quickly assess which classes are missed the most, and into what other class

- Consider classification via ANN + linear threshold unit
- Normally threshold  $f(x; w, b)$  at 0, but what if we changed it?
- Keeping  $w$  fixed while changing threshold = fixing hyperplane's slope while moving along its normal vector

- Get a **set** of classifiers, one per labeling of test set
- Similar situation with any classifier with confidence value, e.g., probability-based

- Consider the “always –” hyp. What is  $fp$ ? What is  $tp$ ?  
What about the “always +” hyp?
- In between the extremes, we plot TP versus FP by  
sorting the test examples by the confidence values

Ex	Confidence	label	Ex	Confidence	label
$x_1$	169.752	+	$x_6$	-12.640	-
$x_2$	109.200	+	$x_7$	-29.124	-
$x_3$	19.210	-	$x_8$	-83.222	-
$x_4$	1.905	+	$x_9$	-91.554	+
$x_5$	-2.75	+	$x_{10}$	-128.212	-

- The **convex hull** of the ROC curve yields a collection of classifiers, each optimal under different conditions
  - If FP cost = FN cost, then draw a line with slope  $|N|/|P|$  at  $(0, 1)$  and drag it towards convex hull until you touch it; that's your **operating point**
  - Can use as a classifier any part of the hull since can randomly select between two classifiers

- Can also compare curves against “single-point” classifiers when no curves
  - In plot, ID3 better than our SVM iff negatives scarce; nB never better

- What is the worst possible ROC curve?
- One metric for measuring a curve's goodness: **area under curve (AUC)**:

$$\frac{\sum_{x_+ \in P} \sum_{x_- \in N} I(h(x_+) > h(x_-))}{|P| |N|}$$

i.e., rank all examples by confidence in “+” prediction, count the number of times a positively-labeled example (from  $P$ ) is ranked above a negatively-labeled one (from  $N$ ), then normalize

- What is the best value?
- Distribution approximately normal if  $|P|, |N| > 10$ , so can find confidence intervals
- Catching on as a better scalar measure of performance than error rate
- Possible (though tricky) with multi-class problems

Consider information retrieval task, e.g., web search

○ All documents    ✓ relevant    × not relevant    ◉ retrieved

**precision** =  $tp/p'$  = fraction of retrieved that are positive

**recall** =  $tp/p$  = fraction of positives retrieved

- As with ROC, vary threshold to trade precision and recall
- Can compare curves based on containment
- More suitable than ROC for large numbers of negatives
- Use  $F_\beta$ -measure to combine at a specific point, where  $\beta$  weights precision vs recall:

$$F_\beta \equiv (1 + \beta^2) \frac{\text{precision} \cdot \text{recall}}{(\beta^2 \cdot \text{precision}) + \text{recall}}$$
