### Introduction

# Computer Science & Engineering 423/823 Design and Analysis of Algorithms

Lecture 06 — Dynamic Programming (Chapter 15)

Stephen Scott (Adapted from Vinodchandran N. Variyam) > Dynamic programming is a technique for solving optimization problems

- Key element: Decompose a problem into subproblems, solve them recursively, and then combine the solutions into a final (optimal) solution
   Important component: There are typically an exponential number of
- subproblems to solve, but many of them overlap ⇒ Can re-use the solutions rather than re-solving them
- Number of distinct subproblems is polynomial

# Rod Cutting (1)

Rod Cutting (2)

p;

- A company has a rod of length n and wants to cut it into smaller rods to maximize profit
- Have a table telling how much they get for rods of various lengths: A rod of length *i* has price p<sub>i</sub>
- ▶ The cuts themselves are free, so profit is based solely on the prices charged for of the rods
- ► If cuts only occur at integral boundaries 1, 2, ..., n − 1, then can make or not make a cut at each of n − 1 positions, so total number of possible solutions is 2<sup>n−1</sup>

9	1 8	5 5	
() ) ) ) ) ) (a)	(b)	()(c)

1 5 8 9 10 17 17 20 24 30

8 9 10

1 2 3 4 5 6 7

### Rod Cutting (3)

► Given a rod of length n, want to find a set of cuts into lengths i<sub>1</sub>,..., i<sub>k</sub> (where i<sub>1</sub> + ··· + i<sub>k</sub> = n) and revenue r<sub>n</sub> = p<sub>i</sub> + ··· + p<sub>ik</sub> is maximized

▶ For a specific value of n, can either make no cuts (revenue = p<sub>n</sub>) or make a cut at some position i, then optimally solve the problem for lengths i and n − i:

 $r_n = \max(p_n, r_1 + r_{n-1}, r_2 + r_{n-2}, \dots, r_i + r_{n-i}, \dots, r_{n-1} + r_1)$ 

- Notice that this problem has the **optimal substructure property**, in that an optimal solution is made up of optimal solutions to subproblems
   Can find optimal solution if we consider all possible subproblems
- ► Alternative formulation: Don't further cut the first segment:

$$r_n = \max_{1 \le i \le n} (p_i + r_{n-i})$$

(ロ)・(書)・(当)・(当)・(ロ)・

### Cut-Rod(p, n)

1 if n == 0 then 2 | return 0 3  $q = -\infty$ 4 for i = 1 to n do 5 |  $q = \max(q, p[i] + \text{CUT-ROD}(p, n - i))$ 6 end 7 return q

### Time Complexity

- Let T(n) be number of calls to CUT-ROD
- Thus T(0) = 1 and, based on the **for** loop,

$$T(n) = 1 + \sum_{j=0}^{n-1} T(j) = 2^n$$

- Why exponential? CUT-ROD exploits the optimal substructure property, but repeats work on these subproblems
- E.g., if the first call is for n = 4, then there will be:
  - ▶ 1 call to CUT-ROD(4)
  - ▶ 1 call to CUT-ROD(3)
  - 2 calls to CUT-ROD(2)
  - ► 4 calls to CUT-ROD(1)
  - ▶ 8 calls to CUT-ROD(0)

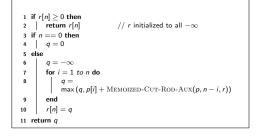

Memoized-Cut-Rod-Aux(p, n, r)

Time Complexity (2)

- Can save time dramatically by remembering results from prior calls
- Two general approaches:
  - 1. **Top-down with memoization:** Run the recursive algorithm as defined earlier, but before recursive call, check to see if the calculation has already been done and **memoized**
  - 2. Bottom-up: Fill in results for "small" subproblems first, then use these to fill in table for "larger" ones
- Typically have the same asymptotic running time

0

Bottom-Up-Cut-Rod(p, n)

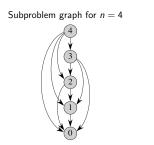

1 Allocate r[0...n]2 r[0] = 03 for j = 1 to n do 4  $q = -\infty$ 5 for i = 1 to j do 6  $| q = \max(q, p[i] + r[j - i])$ 7 end 8 r[j] = q9 end 10 return r[n]

First solves for n = 0, then for n = 1 in terms of r[0], then for n = 2 in terms of r[0] and r[1], etc.

### Example

j = 2 $i = 1$ $i = 2$ $j = 3$ $i = 1$ $i = 2$	$j = 4$ $p_1 + r_0 = 1 = r_1$ $i = 1$ $p_1 + r_3 = 1 + 8 = 9$ $i = 2$ $p_2 + r_2 = 5 + 5 = 10 = r_4$ $i = 3$ $p_3 + r_1 + 8 + 1 = 9$ $i = 4$ $p_4 + r_0 = 9 + 0 = 9$ $p_1 + r_2 = 1 + 5 = 6$ $p_2 + r_1 = 5 + 1 = 6$ $p_3 + r_0 = 8 + 0 = 8 = r_3$

#### Time Complexity

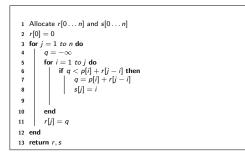

Both algorithms take linear time to solve for each value of n, so total time complexity is  $\Theta(n^2)$ 

・ロト 4番ト 4目ト 目 のQの

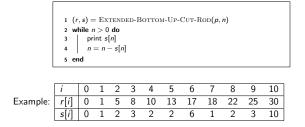

### Reconstructing a Solution

- If interested in the set of cuts for an optimal solution as well as the revenue it generates, just keep track of the choice made to optimize each subproblem
- ▶ Will add a second array *s*, which keeps track of the optimal size of the first piece cut in each subproblem

Extended-Bottom-Up-Cut-Rod(p, n)

# Print-Cut-Rod-Solution(p, n)

If n = 10, optimal solution is no cut; if n = 7, then cut once to get segments of sizes 1 and 6

# Matrix-Chain Multiplication (1)

- $\blacktriangleright$  Given a chain of matrices  $\langle A_1,\ldots,A_n\rangle,$  goal is to compute their product  $A_1\cdots A_n$
- This operation is associative, so can sequence the multiplications in multiple ways and get the same result
- > Can cause dramatic changes in number of operations required
- Multiplying a  $p \times q$  matrix by a  $q \times r$  matrix requires pqr steps and yields a  $p \times r$  matrix for future multiplications
- E.g., Let  $A_1$  be  $10 \times 100$ ,  $A_2$  be  $100 \times 5$ , and  $A_3$  be  $5 \times 50$ 
  - 1. Computing  $((A_1A_2)A_3)$  requires  $10\cdot100\cdot5=5000$  steps to compute  $(A_1A_2)$  (yielding a  $10\times5$ ), and then  $10\cdot5\cdot50=2500$  steps to finish, for a total of 7500
  - 2. Computing  $(A_1(A_2A_3))$  requires  $100 \cdot 5 \cdot 50 = 25000$  steps to compute  $(A_2A_3)$  (yielding a  $100 \times 50$ ), and then  $10 \cdot 100 \cdot 50 = 50000$  steps to finish, for a total of 75000

Matrix-Chain Multiplication (2)

- The matrix-chain multiplication problem is to take a chain  $\langle A_1, \ldots, A_n \rangle$  of *n* matrices, where matrix *i* has dimension  $p_{i-1} \times p_i$ , and fully parenthesize the product  $A_1 \cdots A_n$  so that the number of scalar multiplications is minimized
- Brute force solution is infeasible, since its time complexity is  $\Omega\left(4^n/n^{3/2}\right)$
- Will follow 4-step procedure for dynamic programming:
  - 1. Characterize the structure of an optimal solution
  - 2. Recursively define the value of an optimal solution
  - 3. Compute the value of an optimal solution
  - 4. Construct an optimal solution from computed information

### Characterizing the Structure of an Optimal Solution

- Let  $A_{i...j}$  be the matrix from the product  $A_i A_{i+1} \cdots A_j$
- ► To compute A<sub>i...j</sub>, must split the product and compute A<sub>i...k</sub> and A<sub>k+1...j</sub> for some integer k, then multiply the two together
- Cost is the cost of computing each subproduct plus cost of multiplying the two results
- $\blacktriangleright$  Say that in an optimal parenthesization, the optimal split for  $A_i A_{i+1} \cdots A_j$  is at k
- ► Then in an optimal solution for A<sub>i</sub>A<sub>i+1</sub> ··· A<sub>j</sub>, the parenthisization of A<sub>i</sub> ··· A<sub>k</sub> is itself optimal for the subchain A<sub>i</sub> ··· A<sub>k</sub> (if not, then we could do better for the larger chain)
- Similar argument for  $A_{k+1} \cdots A_j$
- ► Thus if we make the right choice for *k* and then optimally solve the subproblems recursively, we'll end up with an optimal solution
- ▶ Since we don't know optimal k, we'll try them all

### Recursively Defining the Value of an Optimal Solution

- ▶ Define m[i, j] as minimum number of scalar multiplications needed to compute A<sub>i...j</sub>
- (What entry in the m table will be our final answer?)
- Computing m[i, j]:
  - 1. If i = j, then no operations needed and m[i, i] = 0 for all i
  - If i < j and we split at k, then optimal number of operations needed is the optimal number for computing A<sub>i...k</sub> and A<sub>k+1...j</sub>, plus the number to multiply them:

 $m[i,j] = m[i,k] + m[k+1,j] + p_{i-1}p_kp_j$ 

3. Since we don't know k, we'll try all possible values:

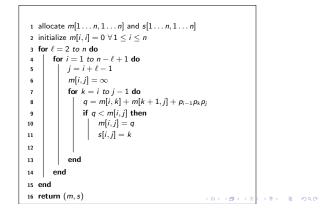

$$m[i,j] = \begin{cases} 0 & \text{if } i = j \\ \min_{i \le k < j} \{m[i,k] + m[k+1,j] + p_{i-1}p_k p_j\} & \text{if } i < j \end{cases}$$

► To track the optimal solution itself, define s[i, j] to be the value of k used at each split

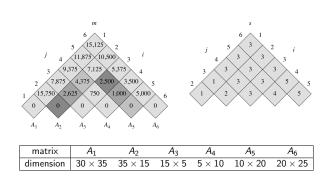

#### Computing the Value of an Optimal Solution

- As with the rod cutting problem, many of the subproblems we've defined will overlap
- Exploiting overlap allows us to solve only Θ(n<sup>2</sup>) problems (one problem for each (i, j) pair), as opposed to exponential
- We'll do a bottom-up implementation, based on chain length
- Chains of length 1 are trivially solved (m[i, i] = 0 for all i)
- ▶ Then solve chains of length 2, 3, etc., up to length n
- $\blacktriangleright$  Linear time to solve each problem, quadratic number of problems, yields  $O(n^3)$  total time

### Matrix-Chain-Order(p, n)

#### Example

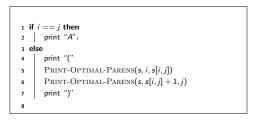

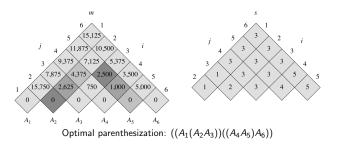

Constructing an Optimal Solution from Computed Information

- ▶ Cost of optimal parenthesization is stored in m[1, n]
- First split in optimal parenthesization is between s[1, n] and s[1, n] + 1
- Descending recursively, next splits are between s[1, s[1, n]] and s[1, s[1, n]] + 1 for left side and between s[s[1, n] + 1, n] and s[s[1, n] + 1, n] + 1 for right side
- and so on...

### Print-Optimal-Parens(s, i, j)

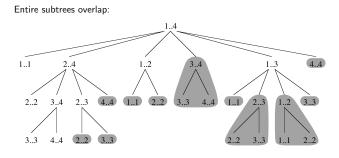

#### Example

ロ> (四> (日)(H)(H

#### Example of How Subproblems Overlap

See Section 15.3 for more on optimal substructure and overlapping subproblems

#### Longest Common Subsequence

- Sequence  $Z = \langle z_1, z_2, \ldots, z_k \rangle$  is a **subsequence** of another sequence  $X = \langle x_1, x_2, \ldots, x_m \rangle$  if there is a strictly increasing sequence  $\langle i_1, \ldots, i_k \rangle$  of indices of X such that for all  $j = 1, \ldots, k$ ,  $x_{i_j} = z_j$
- I.e., as one reads through Z, one can find a match to each symbol of Z in X, in order (though not necessarily contiguous)
- E.g.,  $Z = \langle B, C, D, B \rangle$  is a subsequence of  $X = \langle A, B, C, B, D, A, B \rangle$ since  $z_1 = x_2$ ,  $z_2 = x_3$ ,  $z_3 = x_5$ , and  $z_4 = x_7$
- ► *Z* is a **common subsequence** of *X* and *Y* if it is a subsequence of both
- ► The goal of the longest common subsequence problem is to find a maximum-length common subsequence (LCS) of sequences X = ⟨x<sub>1</sub>, x<sub>2</sub>,..., x<sub>m</sub>⟩ and Y = ⟨y<sub>1</sub>, y<sub>2</sub>,..., y<sub>n</sub>⟩

### Characterizing the Structure of an Optimal Solution

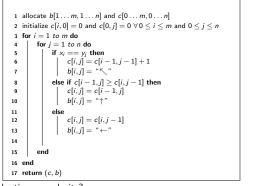

- Given sequence  $X = \langle x_1, \dots, x_m \rangle$ , the *i*th **prefix** of X is  $X_i = \langle x_1, \dots, x_i \rangle$
- **Theorem** If  $X = \langle x_1, \dots, x_m \rangle$  and  $Y = \langle y_1, \dots, y_n \rangle$  have LCS
- $Z = \langle z_1, \dots, z_k \rangle$ , then 1.  $x_m = y_n \Rightarrow z_k = x_m = y_n$  and  $Z_{k-1}$  is LCS of  $X_{m-1}$  and  $Y_{n-1}$ 
  - $If z_k ≠ x_m, can lengthen Z, ⇒ contradiction$ 
    - ▶ If  $Z_{k-1}$  not LCS of  $X_{m-1}$  and  $Y_{n-1}$ , then a longer CS of  $X_{m-1}$  and  $Y_{n-1}$ could have  $x_m$  appended to it to get CS of X and Y that is longer than Z,  $\Rightarrow$  contradiction
  - 2. If  $x_m \neq y_n$ , then  $z_k \neq x_m$  implies that Z is an LCS of  $X_{m-1}$  and Y If  $z_k \neq x_m$ , then Z is a CS of  $X_{m-1}$  and Y. Any CS of  $X_{m-1}$  and Y that is
  - longer than Z would also be a longer CS for X and Y,  $\Rightarrow$  contradiction 3. If  $x_m \neq y_n$ , then  $z_k \neq y_n$  implies that Z is an LCS of X and  $Y_{n-1}$
  - Similar argument to (2)

### Recursively Defining the Value of an Optimal Solution

- ▶ The theorem implies the kinds of subproblems that we'll investigate to find LCS of  $X = \langle x_1, \dots, x_m \rangle$  and  $Y = \langle y_1, \dots, y_m \rangle$
- If  $x_m = y_n$ , then find LCS of  $X_{m-1}$  and  $Y_{n-1}$  and append  $x_m$  (=  $y_n$ ) to it
- If  $x_m \neq y_n$ , then find LCS of X and  $Y_{n-1}$  and find LCS of  $X_{m-1}$  and Y and identify the longest one
- Let c[i, j] =length of LCS of  $X_i$  and  $Y_i$

$$c[i,j] = \begin{cases} 0 & \text{if } i = 0 \text{ or } j = 0\\ c[i-1,j-1] + 1 & \text{if } i, j > 0 \text{ and } x_i = y_j\\ \max(c[i,j-1], c[i-1,j]) & \text{if } i, j > 0 \text{ and } x_i \neq y_j \end{cases}$$

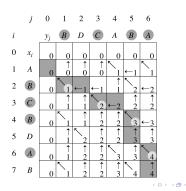

## LCS-Length(X, Y, m, n)

What is the time complexity?

# Example

 $X = \langle A, B, C, B, D, A, B \rangle, \ Y = \langle B, D, C, A, B, A \rangle$ 

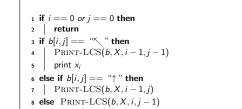

12+12+ 2 940

Constructing an Optimal Solution from Computed Information

# Print-LCS(b, X, i, j)

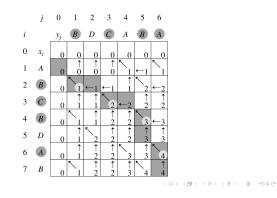

- ▶ Length of LCS is stored in *c*[*m*, *n*]
- ▶ To print LCS, start at *b*[*m*, *n*] and follow arrows until in row or column 0
- If in cell (i, j) on this path, when x<sub>i</sub> = y<sub>j</sub> (i.e., when arrow is "↖"), print x<sub>i</sub> as part of the LCS
- This will print LCS backwards

### Example

 $X = \langle A, B, C, B, D, A, B \rangle$ ,  $Y = \langle B, D, C, A, B, A \rangle$ , prints "BCBA"

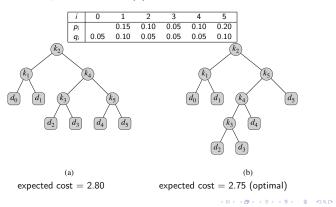

#### **Optimal Binary Search Trees**

- Goal is to construct binary search trees such that most frequently sought values are near the root, thus minimizing expected search time
- $\blacktriangleright$  Given a sequence  $\mathcal{K}=\langle k_1,\ldots,k_n\rangle$  of n distinct keys in sorted order
- Key  $k_i$  has probability  $p_i$  that it will be sought on a particular search
- ▶ To handle searches for values not in K, have n + 1 dummy keys  $d_0, d_1, \ldots, d_n$  to serve as the tree's leaves
- Dummy key  $d_i$  will be reached with probability  $q_i$
- ► If depth<sub>T</sub>(k<sub>i</sub>) is distance from root of k<sub>i</sub> in tree T, then expected search cost of T is

$$1 + \sum_{i=1}^{n} p_i \operatorname{depth}_T(k_i) + \sum_{i=0}^{n} q_i \operatorname{depth}_T(d_i)$$

An optimal binary search tree is one with minimum expected search cost

### Optimal Binary Search Trees (2)

#### Characterizing the Structure of an Optimal Solution

- ▶ Observation: Since K is sorted and dummy keys interspersed in order, any subtree of a BST must contain keys in a contiguous range k<sub>i</sub>,..., k<sub>j</sub> and have leaves d<sub>i-1</sub>,..., d<sub>j</sub>
- Thus, if an optimal BST T has a subtree T' over keys k<sub>i</sub>,..., k<sub>j</sub>, then T' is optimal for the subproblem consisting of only the keys k<sub>i</sub>,..., k<sub>j</sub>
   If T' weren't optimal, then a lower-cost subtree could replace T' in T, ⇒
- Given keys  $k_i, \ldots, k_j$ , say that its optimal BST roots at  $k_r$  for some  $i \le r \le j$
- ▶ Thus if we make right choice for  $k_r$  and optimally solve the problem for  $k_j, \ldots, k_{r-1}$  (with dummy keys  $d_{i-1}, \ldots, d_{r-1}$ ) and the problem for  $k_{r+1}, \ldots, k_j$  (with dummy keys  $d_r, \ldots, d_j$ ), we'll end up with an optimal solution
- Since we don't know optimal k<sub>r</sub>, we'll try them all

contradiction

+□+ +₫+ +∃+ +∃+ -∃ - 900

#### Recursively Defining the Value of an Optimal Solution

- $\blacktriangleright$  Define e[i,j] as the expected cost of searching an optimal BST built on keys  $k_i,\ldots,k_j$
- ▶ If j = i 1, then there is only the dummy key  $d_{i-1}$ , so  $e[i, i 1] = q_{i-1}$
- ▶ If  $j \ge i$ , then choose root  $k_r$  from  $k_i, \ldots, k_j$  and optimally solve subproblems  $k_i, \ldots, k_{r-1}$  and  $k_{r+1}, \ldots, k_j$
- When combining the optimal trees from subproblems and making them children of k<sub>r</sub>, we increase their depth by 1, which increases the cost of each by the sum of the probabilities of its nodes
- Define  $w(i,j) = \sum_{\ell=i}^{j} p_{\ell} + \sum_{\ell=i-1}^{j} q_{\ell}$  as the sum of probabilities of the nodes in the subtree built on  $k_i, \ldots, k_j$ , and get

 $e[i,j] = p_r + (e[i,r-1] + w(i,r-1)) + (e[r+1,j] + w(r+1,j))$ 

#### Recursively Defining the Value of an Optimal Solution (2)

Note that

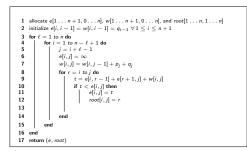

$$w(i,j) = w(i,r-1) + p_r + w(r+1,j)$$

- ► Thus we can condense the equation to e[i,j] = e[i,r-1] + e[r+1,j] + w(i,j)
- Finally, since we don't know what  $k_r$  should be, we try them all:

$$\mathbf{e}[i,j] = \left\{ \begin{array}{ll} q_{i-1} & \text{if } j = i-1 \\ \min_{i \leq r \leq j} \{\mathbf{e}[i,r-1] + \mathbf{e}[r+1,j] + w(i,j)\} & \text{if } i \leq j \end{array} \right.$$

▶ Will also maintain table root[i, j] = index r for which k<sub>r</sub> is root of an optimal BST on keys k<sub>i</sub>,..., k<sub>j</sub>

### Optimal-BST(p, q, n)

What is the time complexity?

うりん 一回 一人回り 人口 マイロー

# Example
